241

Drugs for Parasitic Infections*

With increasing travel, immigration, use of immunosuppressive drugs, and the spread of HIV, physicians anywhere may see infections caused by parasites. The tables that follow list first-choice and alternative drugs for most parasitic infections. [Box 241.1](#) provides the principal adverse effects of these drugs. [Table 241.1](#) summarizes the known prenatal risks of antiparasitic drugs, and [Table 241.2](#) lists brand names and manufacturers of the drugs.

PRINCIPAL ADVERSE EFFECTS OF ANTIPARASITIC DRUGS

Adverse effects of antiparasitic drugs vary with dosage, duration of administration, concomitant therapy, renal and hepatic function, immune

competence, and the age of the patient. The principal adverse effects of antiparasitic agents are listed [Box 241.1](#). The designation of adverse effects as frequent, occasional, or rare is based on published reports and on the experience of *Medical Letter* consultants.

*This chapter is reproduced from: Drugs for parasitic infections. *Med Lett.* 2013;11(suppl):e1–e31. *The Medical Letter* publications are protected by US and international copyright laws. Forwarding, copying or any other distribution of this material is strictly prohibited. For further information call: 800-211-2769.

BOX 241.1 Principal Adverse Effects of Antiparasitic Agents	
Albendazole (Albenza) Frequent: Abdominal pain; increased serum transaminases Occasional: Reversible alopecia; leukopenia Rare: Rash; hepatic toxicity; renal toxicity	Amphotericin B Deoxycholate (Fungizone) Frequent: Renal damage; hypokalemia; thrombophlebitis at site of peripheral vein infusion; anorexia; headache; nausea; weight loss; bone marrow suppression with reversible decline in hematocrit; chills, fever,

BOX 241.1 Principal Adverse Effects of Antiparasitic Agents—cont'd

vomiting during infusion, possibly with delirium, hypotension or hypertension, wheezing, and hypoxemia, especially in cardiac or pulmonary disease

Occasional: Hypomagnesemia; normocytic, normochromic anemia

Rare: Hemorrhagic gastroenteritis, blood dyscrasias, rash, blurred vision, peripheral neuropathy, convulsions, anaphylaxis, arrhythmias, acute liver failure, reversible nephrogenic diabetes insipidus, hearing loss, acute pulmonary edema, spinal cord damage with intrathecal use

Amphotericin B Lipid Formulations (AmBisone, Abelcet, Amphotec)

Similar to amphotericin B but generally better tolerated. Nephrotoxicity is less common and less severe with the lipid-based formulations. Acute infusion reactions are worse with Amphotec, less with Abelcet and least with AmBisome. Liver toxicity has been reported.

Artemether (Artemam)

Occasional: Neurologic toxicity, possible increase in length of coma, increased convulsions, prolongation of QTc interval

Artemether/Lumefantrine (Coatem, Riamet)

Frequent: Abdominal pain, anorexia, headache, dizziness, diarrhea, vomiting, nausea, palpitations, arthralgia, myalgia, asthenia, fatigue, pruritus, rash, sleep disorder, cough

Occasional: Somnolence, involuntary muscle contractions, paresthesia, hypoesthesia, abnormal gait, ataxia

Rare: Hypersensitivity

Artesunate

Occasional: Ataxia, slurred speech, neurological toxicity, possible increase in length of coma, increased convulsions, prolongation of QTc interval

Atovaquone (Mepron, Malarone [With Proguanil])

Frequent: Rash, nausea

Occasional: Diarrhea, increased aminotransferases, cholestasis

Azithromycin (Zithromax)

Occasional: Nausea, diarrhea, abdominal pain, headache, dizziness, vaginitis

Rare: Angioedema, cholestatic jaundice, photosensitivity, reversible dose-related hearing loss, QT prolongation

Benznidazole (Rochagan)

Frequent: Allergic rash, dose-dependent polyneuropathy, GI disturbance, psychic disturbances

Benzyd Alcohol (Ulesfia Lotion)

Frequent: Eye irritation, contact dermatitis

Bithionol (Bitin)

Frequent: Photosensitivity reactions, vomiting, diarrhea, abdominal pain, urticaria

Rare: Leukopenia, toxic hepatitis

Chloroquine HCL and Chloroquine Phosphate (Aralen)

Occasional: Pruritus; vomiting; headache; confusion; depigmentation of hair; skin eruptions; corneal opacity; weight loss; partial alopecia; extraocular muscle palsies; exacerbation of psoriasis, eczema, and other exfoliative dermatoses; myalgias; photophobia

Rare: Irreversible retinal injury (especially when total dosage exceeds 100 g), discoloration of nails and mucous membranes, nerve-type deafness, peripheral neuropathy and myopathy, heart block, blood dyscrasias, hematemesis

Clarithromycin (Biaxin)

Occasional: Nausea, diarrhea, abdominal pain, abnormal taste, headache, dizziness

Rare: Reversible dose-related hearing loss, pseudomembranous colitis, pancreatitis, torsades de pointes

Clindamycin (Cleocin)

Frequent: Diarrhea, allergic reactions

Occasional: Pseudomembranous colitis, sometimes severe, can occur even with topical use

Rare: Blood dyscrasias, esophageal ulceration, hepatotoxicity, arrhythmia due to QTc prolongation

Crotamiton (Eurax)

Occasional: Rash

Dapsone

Frequent: Rash, transient headache, GI irritation, anorexia, infectious mononucleosis-like syndrome

Occasional: Cyanosis due to methemoglobinemia and sulfhemoglobinemia; other blood dyscrasias, including hemolytic anemia; nephrotic syndrome; liver damage; peripheral neuropathy; hypersensitivity reactions; increased risk of lepra reactions; insomnia; irritability; uncoordinated speech; agitation; acute psychosis

Rare: Renal papillary necrosis, severe hypoalbuminemia, epidermal necrolysis, optic atrophy, agranulocytosis, neonatal hyperbilirubinemia after use in pregnancy

Diethylcarbamazine Citrate (Hetrazan)

Frequent: Allergic or febrile reactions, which may be severe, in patients with microfilaria in the blood or the skin; GI disturbance

Rare: Encephalopathy

Diloxanide Furoate (Furamide)

Frequent: Flatulence

Occasional: Nausea, vomiting, diarrhea

Rare: Diplopia, dizziness, urticaria, pruritus

Eflornithine (Difluoromethylornithine, DFMO, Ornidyl)

Frequent: Anemia, leukopenia

Occasional: Diarrhea, thrombocytopenia, seizures

Rare: Hearing loss

Fluconazole (Diflucan)

Occasional: Nausea, vomiting, diarrhea, abdominal pain, headache, rash, increased aminotransferases

Rare: Severe hepatic toxicity, exfoliative dermatitis, anaphylaxis, Stevens-Johnson syndrome, toxic epidermal necrolysis, hair loss

Flucytosine (Ancobon)

Frequent: Blood dyscrasias, including pancytopenia and fatal agranulocytosis; GI disturbance, including severe diarrhea and ulcerative colitis; rash; hepatic dysfunction

Occasional: Confusion, hallucinations

Rare: Anaphylaxis

Furazolidone (Furoxone)

Frequent: Nausea, vomiting

Occasional: Allergic reactions, including pulmonary infiltration, hypotension, urticaria, fever, vesicular rash, hypoglycemia, headache

Rare: Hemolytic anemia in G6PD deficiency and neonates, disulfiram-like reaction with alcohol, MAO-inhibitor interactions, polyneuritis

BOX 241.1 Principal Adverse Effects of Antiparasitic Agents—cont'd**Iodoquinol (Yodoxin, and generics)**

Occasional: Rash, acne, slight enlargement of the thyroid gland, nausea, diarrhea, cramps, anal pruritus

Rare: Optic neuritis, atrophy and loss of vision, peripheral neuropathy after prolonged use in high dosage (for months), iodine sensitivity

itraconazole (Sporanox, and generics)

Occasional: Nausea, epigastric pain, headache, dizziness, edema, hypokalemia, rash, hepatic toxicity

Rare: Congestive heart failure

Ivermectin, Oral (Stromectol)

Occasional: Mazzotti-type reaction seen in onchocerciasis, including fever; pruritus; tender lymph nodes; headache; and joint and bone pain

Rare: Hypotension

Ivermectin, Lotion (Sklice)

Occasional: Conjunctivitis, ocular hyperemia, eye irritation, dandruff, burning sensation of the skin

Ketoconazole (Nizoral)

Frequent: Nausea, vomiting

Occasional: Decreased testosterone synthesis, gynecomastia, oligospermia and impotence in men, abdominal pain, rash, hepatitis, pruritus, dizziness, constipation, diarrhea, fever and chills, photophobia, headache

Rare: Fatal hepatic necrosis, liver injury with jaundice, transient elevated transaminase, severe epigastric burning and pain, interference with adrenal function, anaphylaxis

Malathion (Ovide)

Occasional: Local irritation

Mebendazole (Vermox)

Occasional: Diarrhea, abdominal pain

Rare: Leukopenia, agranulocytosis, hypospermia

Mefloquine (Lariam)

Frequent: Vertigo, lightheadedness, nausea, other GI disturbances, nightmares, visual disturbances, headache, insomnia

Occasional: Confusion

Rare: Psychosis, hypotension, convulsions, coma, paresthesias

Meglumine Antimoniate (Glucantime)

Similar to sodium stibogluconate

Melarsoprol (Mel B)

Frequent: Myocardial damage, albuminuria, hypertension, colic, Herxheimer-type reaction, encephalopathy, vomiting, peripheral neuropathy

Rare: Shock

Metronidazole (Flagyl)

Frequent: Nausea, headache, anorexia, metallic taste

Occasional: Vomiting, diarrhea, insomnia, weakness, dry mouth, stomatitis, vertigo, tinnitus, paresthesias, rash, dark urine, urethral burning, disulfiram-like reaction with alcohol, candidiasis

Rare: Pseudomembranous colitis; leukopenia; pancreatitis; seizures; peripheral neuropathy; encephalopathy; cerebellar syndrome with ataxia, dysarthria, and MRI abnormalities

Miconazole (Monistat)

Occasional: Phlebitis, thrombocytosis, chills, intense, persistent pruritus, rash, vomiting, hyperlipidemia, dizziness, blurred vision, local burning and irritation with topical use

Rare: Anemia, thrombocytopenia, hyponatremia, renal insufficiency, anaphylaxis, cardiac and respiratory arrest with initial dose

Miltefosine (Impavido)

Frequent: Nausea, vomiting, diarrhea, motion sickness, increased creatinine

Niclosamide (Niclocide)

Occasional: Nausea, abdominal pain

Nifurtimox (Lampit)

Frequent: Anorexia, nausea, vomiting, gastric pain, insomnia, headache, vertigo, excitability, myalgia, arthralgia, peripheral polyneuritis

Rare: Convulsions, fever, pulmonary infiltrates, pleural effusion

Nitazoxanide (Alinia)

Occasional: GI disturbance, headache

Rare: Yellow discoloration of sclera, allergic reactions, increased creatinine, dizziness, flatulence, malaise, salivary gland enlargement, discolored urine, anemia, leukytosis

Ornidazole (Tiberal)

Occasional: Dizziness, headache, GI disturbance

Rare: Reversible peripheral neuropathy

Oxamniquine (Vansil)

Occasional: Headache, fever, dizziness, somnolence and insomnia, nausea, diarrhea, rash, increased aminotransferases, ECG changes, EEG changes, orange-red discoloration of urine

Rare: Seizures, neuropsychiatric disturbances

Paromomycin (Aminosidine, Humatin)

Frequent: GI disturbance with oral use

Rare: Eighth cranial nerve damage (mainly auditory) and renal damage when aminosidine is given IV, vertigo, pancreatitis

Pentamidine Isethionate (Pentam 300, NebuPent)

Frequent: Hypotension, hypoglycemia often followed by diabetes mellitus, vomiting, blood dyscrasias, renal damage, pain at injection site, GI disturbance

Occasional: May aggravate diabetes, shock, hypocalcemia, liver damage, cardiotoxicity, delirium, rash

Rare: Herxheimer-type reaction, anaphylaxis, acute pancreatitis, hyperkalemia

Permethrin (Nix)

Occasional: Burning, stinging, numbness, increased pruritus, pain, edema, erythema, rash

Praziquantel (Biltricide)

Frequent: Abdominal pain, diarrhea, malaise, headache, dizziness

Occasional: Sedation, fever, sweating, nausea, eosinophilia

Rare: Pruritus, rash, edema, hiccups

Primaquine Phosphate

Frequent: Hemolytic anemia in G6PD deficiency

Occasional: Neutropenia, GI disturbance, methemoglobinemia

Rare: CNS symptoms, hypertension, arrhythmias

Proguanil (Paludrine, Malarone [With Atovaquone])

Occasional: Oral ulceration, hair loss, scaling of palms and soles, urticaria

Rare: Hematuria (with large doses), vomiting, abdominal pain, diarrhea (with large doses), thrombocytopenia

BOX 241.1 Principal Adverse Effects of Antiparasitic Agents—cont'd**Pyrantel Pamoate (Antiminth)****Occasional:** GI disturbance, headache, dizziness, rash, fever**Pyrethrins With Piperonyl Butoxide (A-200)****Occasional:** Allergic reactions**Pyrimethamine (Daraprim)****Occasional:** Blood dyscrasias, folic acid deficiency**Rare:** Rash, vomiting, convulsions, shock, possibly pulmonary eosinophilia, fatal cutaneous reactions with pyrimethamine-sulfadoxine (Fansidar)**Quinacrine****Frequent:** Disulfiram-like reaction with alcohol, nausea and vomiting, colors skin and urine yellow**Occasional:** Headache, dizziness**Rare:** Rash, fever, psychosis, extensive exfoliative dermatitis in patients with psoriasis**Quinine Dihydrochloride and Quinine Sulfate****Frequent:** Cinchonism (tinnitus, headache, nausea, abdominal pain, visual disturbance)**Occasional:** Deafness, hemolytic anemia, other blood dyscrasias, photosensitivity reactions, hypoglycemia, arrhythmias, hypotension, fever**Rare:** Blindness, sudden death if injected too rapidly, hypersensitivity reaction with TTP-HUS**Sodium Stibogluconate (Pentostam)****Frequent:** Myalgia and arthralgia (typically, large joint, may or may not be symmetric); malaise, fatigue, and weakness; headache; anorexia; nausea; increased aminotransferases; increased amylase and lipase; T-wave flattening or inversion**Occasional:** Abdominal pain, liver damage, bradycardia, leukopenia, thrombocytopenia, rash, vomiting**Rare:** Diarrhea, pruritus, myocardial damage, hemolytic anemia, renal damage, shock, sudden death**Spiramycin (Rovamycine)****Occasional:** GI disturbance**Rare:** Allergic reactions**Sulfonamides****Frequent:** Allergic reactions (rash, photosensitivity, drug fever)**Occasional:** Kernicterus in newborn, renal damage, liver damage, Stevens-Johnson syndrome (particularly with long-acting sulfonamides), hemolytic anemia, other blood dyscrasias, vasculitis**Rare:** Transient acute myopia, pseudomembranous colitis, reversible infertility in men with sulfasalazine, CNS toxicity with trimethoprim-sulfamethoxazole in patients with AIDS**Suramin Sodium****Frequent:** Vomiting, pruritus, urticaria, paresthesias, hyperesthesia of hands and feet, peripheral neuropathy, photophobia**Occasional:** Kidney damage, blood dyscrasias, shock, optic atrophy**Tetracyclines (Doxycycline [Vibramycin], Tetracycline Hydrochloride [Sumycin])****Frequent:** GI disturbance, bone lesions and staining and deformity of teeth in children age ≤ 8 years and in the newborn when given to pregnant women after the fourth month of pregnancy**Occasional:** Malabsorption; enterocolitis; photosensitivity reactions; increased azotemia with renal insufficiency (except doxycycline, but exacerbation of renal failure with doxycycline has been reported); hepatic injury; parenteral doses may cause serious liver damage, especially in pregnant women and patients with renal disease receiving ≥ 1 g daily; esophageal ulcerations; cutaneous and mucosal hyperpigmentation**Rare:** Allergic reactions, including serum sickness and anaphylaxis; pseudomembranous colitis; blood dyscrasias; drug-induced lupus; autoimmune hepatitis; increased intracranial pressure; fixed-drug eruptions; transient acute myopia; blurred vision; diplopia; papilledema; photoonycholysis and onycholysis; aggravation of myasthenic symptoms with IV injection, reversed with calcium; possibly transient neuropathy; hemolytic anemia**Tinidazole (Tindamax)****Occasional:** Metallic taste, GI symptoms, rash**Rare:** Weakness**Trimethoprim (Proloprim)****Frequent:** Nausea and vomiting with high doses**Occasional:** Megaloblastic anemia, thrombocytopenia, neutropenia, rash, fixed drug eruption**Rare:** Pancytopenia, hyperkalemia**Trimethoprim/Sulfamethoxazole (Bactrim, Septra)****Frequent:** Rash, fever, nausea and vomiting**Occasional:** Hemolysis in G6PD deficiency, acute megaloblastic anemia, granulocytopenia, thrombocytopenia, pseudomembranous colitis, kernicterus in newborn, hyperkalemia**Rare:** Agranulocytosis, aplastic anemia, hepatotoxicity, Stevens-Johnson syndrome, aseptic meningitis, fever, confusion, depression, hallucinations, deterioration in renal disease, intrahepatic cholestasis, methemoglobinemia, pancreatitis, ataxia, CNS toxicity in patients with AIDS, renal tubular acidosis, hyperkalemia

AIDS, Acquired immunodeficiency syndrome; *CNS*, central nervous system; *ECG*, electrocardiogram; *EEG*, electroencephalogram; *G6PD*, glucose-6 phosphate dehydrogenase; *GI*, gastrointestinal; *IV*, intravenous; *MAO*, monoamine oxidase; *MRI*, magnetic resonance imaging; *TTP-HUS*, thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome.

TABLE 241.1 Safety of Antiparasitic Drugs in Pregnancy

Drug	Toxicity in Pregnancy	Recommendations	FDA
Albendazole (Albenza)	Teratogenic and embryotoxic in animals	Caution*; contraindicated for long-term use	C
Amphotericin B (Fungizone)	None known	Caution*	B
Amphotericin B liposomal (AmBisome)	None known	Caution*	B
Artemether/lumefantrine (Coartem, Riamet) ¹	Embryo-fetal loss in rats and rabbits	Contraindicated during 1st trimester; caution 2nd and 3rd trimesters*	C
Artesunate ¹	Embryocidal and teratogenic in rats	Contraindicated during 1st trimester; caution 2nd and 3rd trimesters*	NA

Continued

TABLE 241.1 Safety of Antiparasitic Drugs in Pregnancy—cont'd

Drug	Toxicity in Pregnancy	Recommendations	FDA
Atovaquone (Mepron)	Maternal and fetal toxicity in animals	Caution*	C
Atovaquone/proguanil (Malarone) ²	Maternal and fetal toxicity in animals	Caution*	C
Azithromycin (Zithromax)	None known	Probably safe	B
Benznidazole (Rochagan)	Unknown	Contraindicated	NA
Benzyl alcohol lotion (Ulesfia Lotion)	Unknown	Probably safe	B
Chloroquine (Aralen)	None known with doses recommended for malaria prophylaxis	Probably safe in low doses	C
Clarithromycin (Biaxin)	Teratogenic in animals	Contraindicated	C
Clindamycin (Cleocin)	None known	Caution*	B
Crotamiton (Eurax)	Unknown	Caution*	C
Dapsone	None known; carcinogenic in rats and mice; hemolytic reactions in neonates	Caution,* especially at term	C
Diethylcarbamazine (DEC; Hetrazan)	Not known; abortifacient in one study in rabbits	Contraindicated	NA
Diloxanide (Furamide)	Safety not established	Caution*	NA
Doxycycline (Vibramycin)	Tooth discoloration and dysplasia inhibition of bone growth in fetus; hepatic toxicity and azotemia with IV use in pregnant patients with decreased renal function or with overdosage	Contraindicated	D
Eflornithine (Ornidyl)	Embryocidal in animals	Contraindicated	C
Fluconazole (Diflucan)	Teratogenic	Contraindicated for high dose; caution* for single dose	C
Flucytosine (Ancoban)	Teratogenic in rats	Contraindicated	C
Furazolidone (Furoxone)	None known; carcinogenic in rodents; hemolysis with G6PD deficiency in newborn	Caution*; contraindicated at term	NA
Hydroxychloroquine (Plaquenil)	None known with doses recommended for malaria prophylaxis	Probably safe in low doses	C
Itraconazole (Sporanox)	Teratogenic and embryotoxic in rats	Caution*	C
Iodoquinol (Yodoxin)	Unknown	Caution*	C
Ivermectin (Sklice, Stromectol) ³	Teratogenic in animals	Contraindicated	C
Ketoconazole (Nizoral)	Teratogenic and embryotoxic in rats	Contraindicated; topical probably safe	C
Lindane	Absorbed from the skin; potential CNS toxicity in fetus	Contraindicated	C
Malathion, topical (Ovide)	None known	Probably safe	B
Mebendazole (Vermox)	Teratogenic and embryotoxic in rats	Caution*	C
Mefloquine (Lariam) ⁴	Teratogenic in animals	Caution*	B
Meglumine (Glucantime)	Not known	Caution*	NA
Metronidazole (Flagyl)	None known; carcinogenic in rats and mice	Caution*	B
Miconazole (Monistat)	None known	Caution*	C
Miltefosine (Impavido)	Teratogenic in rats and induces abortions in animals	Contraindicated; effective contraception must be used for 2 months after the last dose	NA
Niclosamide (Nicolcide)	Not absorbed; no known toxicity in fetus	Probably safe	B
Nifurtimox (Lampit)	Retarded growth in rats and mice	Caution*; contraindicated during 1st trimester	NA
Nitazoxanide (Alinia)	None known	Probably safe	B
Oxamniquine (Vansil)	Embryocidal in animals	Contraindicated	NA
Paromomycin	Poorly absorbed; toxicity in fetus unknown	Oral capsules probably safe	C
Pentamidine (Pentam 300, NebuPent)	Safety not established	Caution*	C
Permethrin (Nix)	Poorly absorbed; no known toxicity in fetus	Probably safe	B
Praziquantel (Biltricide)	None known	Caution	B
Primaquine	Hemolysis in G6PD deficiency	Contraindicated	C
Pyrantel pamoate (Antiminth)	Absorbed in small amounts; no known toxicity in fetus	Probably safe	C
Pyrethrins and piperonyl butoxide (A-200)	Poorly absorbed; no known toxicity in fetus	Probably safe	C
Pyrimethamine (Daraprim) ⁵	Teratogenic in animals	Caution*; contraindicated during 1st trimester	C
Quinacrine (Atabrine)	Safety not established	Caution*	NA
Quinidine	Large doses can cause abortion	Probably safe	C
Quinine (Qualaquin)	Large doses can cause abortion; auditory nerve hypoplasia, deafness in fetus; visual changes, limb anomalies, visceral defects also reported	Caution*	C
Sodium stibogluconate (Pentostam)	Not known	Caution*	NA
Spiramycin (Rovamycine) ⁵	None known	Probably safe	NA
Sulfonamides	Teratogenic in some animal studies; hemolysis in newborn with G6PD deficiency; increased risk of kernicterus in newborn	Caution*; contraindicated at term	C
Suramin sodium (Germanin)	Teratogenic in mice	Caution*	NA

TABLE 241.1 Safety of Antiparasitic Drugs in Pregnancy—cont'd

Drug	Toxicity in Pregnancy	Recommendations	FDA
Tetracycline (Sumycin)	Tooth discoloration and dysplasia, inhibition of bone growth in fetus; hepatic toxicity and azotemia with IV use in pregnant patients with decreased renal function or with overdosage	Contraindicated	D
Tinidazole (Tindamax)	Increased fetal mortality in rats	Caution*	C
Trimethoprim	Folate antagonism; teratogenic in rats	Caution*	C
Trimethoprim/sulfamethoxazole (Bactrim)	Same as sulfonamides and trimethoprim	Caution*; contraindicated at term	C

CNS, Central nervous system; FDA, US Food and Drug Administration; *G6PD*, glucose-6-phosphate dehydrogenase; IV, intravenous; NA, FDA pregnancy category not available.

*Use only for strong clinical indication in absence of suitable alternative.

1. Based on the few studies available, artemesinins have been relatively safe during pregnancy (Adam I, et al. *Am Trop Med Parasitol.* 2009;103:205), but some experts would not prescribe them in the 1st trimester (Clark RL. *Reprod Toxicol.* 2009;28:285; Manyando C, et al. *Malaria J.* 2012;11:141).

2. Safety in pregnancy is unknown; in a few small studies, outcomes were normal in women treated with the combination in the 2nd and 3rd trimester (Boggild AK, et al. *Am J Trop Med Hyg.* 2007;76:208).

3. Ivermectin has been inadvertently given to pregnant women during mass treatment programs; the rates of congenital abnormalities were similar in treated and untreated women. Because of the high risk of blindness from onchocerciasis, the use of ivermectin after the first trimester is considered acceptable according to the World Health Organization.

4. Mefloquine can be used for prophylaxis or treatment of malaria in pregnant women based on a review of published data (Schlagenhauf P, et al. *Clin Infect Dis.* 2012;54:e124).

5. Women who develop toxoplasmosis during the first trimester of pregnancy should be treated with spiramycin (3–4 g/d). After the first trimester, if there is no documented transmission to the fetus, spiramycin can be continued until term. If transmission has occurred in utero, therapy with pyrimethamine and sulfadiazine should be started. Pyrimethamine is a potential teratogen and should be used only after the first trimester (Montoya JG, Remington JS. *Clin Infect Dis.* 2008;47:554).

TABLE 241.2 Manufacturers of Drugs Used to Treat Parasitic Infections

Generic Name	Brand Name	Manufacturer	Generic Name	Brand Name	Manufacturer
albendazole	Albenza	Amedra	meglumine antimonate ¹	Glucantime	Sanofi, France
amphotericin B	Fungizone, generics	X-Gen	melarsopro ²	Mel-B	
amphotericin B, liposomal	AmBisome	Gilead	metronidazole	Flagyl	Pfizer
artemether ¹	Artemam	Arenco, Belgium	miconazole ¹	Monistat	
artemether/lumefantrine	Coartem, Riamet	Novartis	Miltefosine ^{2,3}	Impavido, Miltex	Paladin, Canada
artesunate ²		Guilin, Shanghai	niclosamide ¹	Yomesan	
atovaquone	Mepron	GlaxoSmithKline	nifurtimox ²	Lampit	Bayer HealthCare
atovaquone/proguanil	Malarone	GlaxoSmithKline	nitazoxanide	Alinia	Romark
azithromycin	Zithromax	Pfizer	ornidazole ¹	Tiberal	
benznidazole ²	Rochagan		oxamniquine ¹	Vansil, Mansil	Pfizer, UK
bithionol ¹	Bitin		paromomycin ¹	Leshcutan (topical)	Sun Pharma
chloroquine	Aralen	Sanofi	pentamidine isethionate	Pentam 300, NebuPent	APP Pharmaceuticals
clarithromycin	Biaxin	Abbvie	permethrin	Nix	Insight, Bayer
clindamycin	Cleocin	Pfizer		Elimite	Renaissance Pharma
crotamiton	Eurax	Ranbaxy	piperazine/ dihydroartemisin	Euratesim	Sigma Tau, Italy
dapsone		Jacobus	praziquantel	Biltricide	Bayer
diethylcarbamazine citrate (DEC) ²	Hetrazan		primaquine phosphate USP		Sanofi
dihydroartemisin/ piperazine	Euratesim	Sigma-Tau, Italy	proguanil ¹	Paludrine	
dioxanide furoate ¹	Furamide, Entamide		proguanil/atovaquone	Malarone	GlaxoSmithKline
doxycycline	Vibramycin	Pfizer	propamidine isethionate ¹	Brolene	Aventis

mefloquine			triclabendazole ¹	Egaten	Novartis
			trimetrexate ¹	Neutrexin	

1. Not available in the United States; may be available through a compounding pharmacy such as Expert Compounding Pharmacy, 6744 Balboa Blvd, Lake Balboa, CA (800-247-9767) or Medical Center Pharmacy, New Haven, CT (203-688-7064). Other compounding pharmacies may be found through the National Association of Compounding Pharmacies (800-687-7850) or the Professional Compounding Centers of America (800-331-2498, www.pccarx.com).

2. Available from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; 404-639-3670 (evenings, weekends, or holidays: 770-488-7100; fax: 404-639-3717).

3. Available from the CDC for treatment of infections with free-living amebae; available from the manufacturer through an IND application from the FDA for treatment of other infections.

Acanthamoeba Keratitis

Drug of choice Keratitis is typically associated with contact lens use.¹ A topical biguanide, 0.02% chlorhexidine or polyhexamethylene biguanide (PHMB, 0.02%), either alone or combined with a diamidine, propamidine isethionate (Brolene) or hexamidine (Desomodine), have been used successfully.² They are administered hourly (or alternating every half hour) day and night for the first 48 hours and then continued on a reduced schedule for days to months.³ None of these drugs is commercially available or approved for use in the United States, but they can be obtained from compounding pharmacies. Leiter's Park Avenue Pharmacy, San Jose, CA (800-292-6773; www.leiterrx.com) is a compounding pharmacy that specializes in ophthalmic drugs. Expert Compounding Pharmacy, 6744 Balboa Blvd., Lake Balboa, CA 91406 (800-247-9767) and Medical Center Pharmacy, New Haven, CT (203-688-7064) are also compounding pharmacies. Other compounding pharmacies may be found through the National Association of Compounding Pharmacies (800-687-7850) or the Professional Compounding Centers of America (800-331-2498, www.pccarx.com). Propamidine is available over the counter in the United Kingdom and Australia. Hexamidine is available in France. Debridement is most useful during the stage of corneal epithelial infection; keratoplasty in medically unresponsive keratitis was successful in 31 eyes in 30 patients.⁴ Most cysts are resistant to neomycin; its use is no longer recommended. Azole antifungal drugs (ketoconazole, itraconazole) have been used as oral or topical adjuncts. Successful treatment with topical or oral voriconazole has been reported in a small number of patients who had not responded to PHMB, chlorhexidine, and hexamidine.^{5,6} Use of corticosteroids is controversial. Prolonged therapy (≥6 months) may be necessary.²

Amebiasis (*Entamoeba histolytica*)

	Drug	Adult Dosage	Pediatric Dosage
Asymptomatic			
Drug of choice:	Iodoquinol ¹	650 mg PO tid × 20 d	30–40 mg/kg/d (max 2 g) PO in 3 doses × 20 d
Or	Paromomycin ²	25–35 mg/kg/d PO in 3 doses × 7 d	25–35 mg/kg/d PO in 3 doses × 7 d
Or	Diloxanide furoate ^{3*}	500 mg PO tid × 10 d	20 mg/kg/d PO in 3 doses × 10 d
Mild to Moderate Intestinal Disease			
Drug of choice ⁴ :	Metronidazole	500–750 mg PO tid × 7–10 d	35–50 mg/kg/d PO in 3 doses × 7–10 d
Or	Tinidazole ⁵	2 g once PO daily × 3 d	>3 y: 50 mg/kg/d (max 2 g) PO in 1 dose × 3 d
Followed by	Iodoquinol ¹	650 mg PO tid × 20 d	30–40 mg/kg/d (max 2 g) PO in 3 doses × 20 d
Or	Paromomycin ²	25–35 mg/kg/d PO in 3 doses × 7 d	25–35 mg/kg/d PO in 3 doses × 7 d
Severe Intestinal and Extraintestinal Disease			
Drug of choice:	Metronidazole	750 mg PO (or IV) tid × 7–10 d	35–50 mg/kg/d PO (or IV) in 3 doses × 7–10 d
Or	Tinidazole ⁵	2 g once PO daily × 5 d	>3 y: 50 mg/kg/d (max 2 g) PO in 1 dose × 5 d
Followed by	Iodoquinol ¹	650 mg PO tid × 20 d	30–40 mg/kg/d (max 2 g) PO in 3 doses × 20 d
Or	Paromomycin ²	25–35 mg/kg/d PO in 3 doses × 7 d	25–35 mg/kg/d PO in 3 doses × 7 d

*Availability problems. See Table 241.1.

1. Iodoquinol should be taken after meals.

2. Paromomycin should be taken with a meal.

3. Not available commercially. It may be obtained through compounding pharmacies such as Expert Compounding Pharmacy, 6744 Balboa Blvd, Lake Balboa, CA 91406 (800-247-9767) or Medical Center Pharmacy, New Haven, CT (203-688-7064). Other compounding pharmacies may be found through the National Association of Compounding Pharmacies (800-687-7850) or the Professional Compounding Centers of America (800-331-2498, www.pccarx.com).

4. Nitazoxanide may be effective against a variety of protozoan and helminth infections (Bobak DA. *Curr Infect Dis Rep*. 2006;8:91; Diaz E, et al. *Am J Trop Med Hyg*. 2003;68:384). It is effective against mild to moderate amebiasis, 500 mg PO bid × 3 d (Rossignol JF, et al. *Trans R Soc Trop Med Hyg*. 2007;101:1025; Escobedo AE, et al. *Arch Dis Child*. 2009;94:478), but perhaps less so than metronidazole (Becker S, et al. *Am J Trop Hyg*. 2011;84:581). Nitazoxanide is FDA approved only for treatment of diarrhea caused by *Giardia* or *Cryptosporidium* (*Med Lett Drugs Ther*. 2003;45:29). It is available in 500-mg tablets and an oral suspension and should be taken with food.

5. Tinidazole, a nitroimidazole similar to metronidazole, appears to be as effective as metronidazole and better tolerated (*Med Lett Drugs Ther*. 2004;46:70). It should be taken with food to minimize adverse GI effects. For children and patients unable to take tablets, a pharmacist can crush the tablets and mix them with cherry syrup (Humco, and others). The syrup suspension is good for 7 days at room temperature and must be shaken before use (Fung HB, Doan TL. *Clin Ther*. 2005;27:1859). Ornidazole, a similar drug, is also used outside the United States.

Amebic Meningoencephalitis, Primary and Granulomatous¹

Drug		Adult Dosage	Pediatric Dosage
Primary Amebic Meningoencephalitis (PAM): <i>Naegleria fowleri</i>^{2,3}			
Drug of choice:	Amphotericin B (conventional formulation) ⁴	0.25 mg/kg IV over 4–6 h. If tolerated, 0.5 mg/kg IV the following day, increasing to 1.5 mg/kg IV once/d as tolerated (max 1.5 mg/kg/d)	0.25 mg/kg IV over 4–6 h. If tolerated, 0.5 mg/kg IV the following day, increasing to 1.5 mg/kg IV once/d as tolerated (max 1.5 mg/kg/d)
Or		1 mg/kg IV once/d plus 0.5 mg/d intraventricularly (can start with 0.025–0.050 mg/d and increase to 0.5 mg/d) ⁵ (max 1.5 mg/kg once/d total dosage by both IV and intraventricular routes)	1 mg/kg IV once/d plus 0.5 mg/d intraventricularly (can start with 0.025–0.050 mg/d and increase to 0.5 mg/d) ⁵ (max 1.5 mg/kg once/d total dosage by both IV and intraventricular routes)
	Rifampin	10 mg/kg IV once/d (max 600 mg/d)	10 mg/kg IV once/d (max 600 mg/d)
	Fluconazole	12 mg/kg IV once/d	12 mg/kg IV once/d
	Azithromycin	500 mg IV once/d	20 mg/kg IV once/d (max 500 mg/d)
Granulomatous Amebic Encephalitis (GAE): <i>Acanthamoeba</i> spp.^{6–8}			
	Pentamidine ⁹	4 mg/kg IV once/d	4 mg/kg IV once/d
	Sulfadiazine	1.5 g q6h PO	200 mg/kg/d PO in 4–6 doses (max 6 g/d)
	Flucytosine	37.5 mg/kg PO q6h (max 150 mg/kg/d)	37.5 mg/kg PO q6h (max 150 mg/kg/d)
	Fluconazole	12 mg/kg IV once/d	12 mg/kg IV once/d
	Miltefosine ¹⁰	<45 kg: 100 mg/d PO in 2 doses ≥45 kg: 150 mg/d PO in 3 doses	2.5 mg/kg/d PO in 2 doses (max 100 mg/d)
Granulomatous Amebic Encephalitis (GAE): <i>Balamuthia mandrillaris</i>^{11–16}			
	Azithromycin	500 mg IV once/d	20 mg/kg IV once/d (max 500 mg/d)
	Clarithromycin	14 mg/kg/d PO in 2 doses (max 2 g/d)	14 mg/kg/d PO in 2 doses (max 2 g/d)
	Pentamidine ⁹	4 mg/kg IV once/d	4 mg/kg IV once/d
	Sulfadiazine	1.5 g PO q6h	200 mg/kg/d PO in 4–6 doses (max 6 g/d)
	Flucytosine	37.5 mg/kg PO q6h (max 150 mg/kg/d)	37.5 mg/kg PO q6h (max 150 mg/kg/d)
	Fluconazole	12 mg/kg IV once/d	12 mg/kg IV once/d
	Miltefosine ¹⁰	<45 kg: 100 mg/d PO in 2 doses ≥45 kg: 150 mg/d PO in 3 doses	2.5 mg/kg/d PO in 2 doses (max 100 mg/d)

1. Meningoencephalitis caused by the free-living amebae *Naegleria fowleri*, *Acanthamoeba* spp., and *Balamuthia mandrillaris* has a mortality rate of >90%; effective treatment has not been established. Treatment recommendations are based on case reports of survivors, animal studies, and in vitro drug testing. Treatment decisions must be tailored to the clinical situation of each patient. Diagnostic assistance, specimen collection guidance, shipping instructions, and treatment recommendations are available through the CDC Emergency Operations Center at 770-488-7100.

2. Seidel JS, et al. *N Engl J Med*. 1982;306:346.

3. Vargas-Zepeda J, et al. *Arch Med Res*. 2005;36:83.

4. Although liposomal amphotericin B crosses the blood-brain barrier better than conventional amphotericin, it has been found to be less effective against PAM caused by *Naegleria fowleri* in mice. Amphotericin B methyl ester was also found to be less effective in the mouse model (Schuster FL, Visvesvara GS. *Int J Parasitol*. 2004;34:1001). Because of the extremely poor prognosis of PAM due to *Naegleria fowleri*, aggressive treatment, including the use of intraventricular amphotericin, should be considered.

5. Chapman SW, et al. In: Kauffman C, ed. *Essentials of Clinical Mycology*. 2nd ed. New York: Springer; 2011:41–55.

6. Immunocompromised patients with cutaneous acanthamoebiasis have been successfully treated with (1) pentamidine, flucytosine, and azithromycin in combination with topical chlorhexidine and 2% ketoconazole cream (Oliva S, et al. *South Med J*. 1999;92:55); (2) pentamidine in combination with topical chlorhexidine and 2% ketoconazole cream followed by oral itraconazole (Slater CA, et al. *N Engl J Med*. 1994;331:85); and (3) amphotericin B lipid complex and voriconazole (Walia R, et al. *Transplant Soc*. 2007;9:51). Miltefosine, both oral and topical, has also shown success in treating cutaneous disease (Aichelburg AC, et al. *Emerg Infect Dis*. 2008;14:1743; Walochnik J, et al. *J Antimicrob Chemother*. 2009;64:539).

7. Aichelburg AC, et al. *Emerg Infect Dis*. 2008;14:1743.

8. Seijo Martinez M, et al. *J Clinical Microbiol*. 2000;38:3892.

9. Addition of pentamidine is based on clinical judgement. Although it has good amebicidal activity in vitro and has been used successfully in the past to treat GAE in combination with the drugs listed, pentamidine is associated with adverse effects, including nephrotoxicity, leukopenia, elevated liver enzymes, and hypoglycemia. Additionally, pentamidine does not cross the normal, intact blood-brain barrier well.

10. Miltefosine is not approved for any indication in the United States. Case reports and in vitro data suggest it may have some antiamebic activity (Aichelburg AC, et al. *Emerg Infect Dis*. 2008;14:1743; Martinez DY, et al. *Infect Dis Soc Am*. 2010;51:e7; Schuster FL, et al. *J Eukaryot Microbiol*. 2006;53:121). Miltefosine (Impavido) is manufactured in 10- or 50-mg capsules by Paladin (Canada) and is available in the United States from the CDC for treatment of infections with free-living amebae. The drug is contraindicated in breastfeeding and pregnant women; a negative pregnancy test before drug initiation and effective contraception during and for 4 months after treatment is recommended (Murray HW, et al. *Lancet*. 2005;366:1561).

***Ancylostoma caninum* (Eosinophilic Enterocolitis)**

Drug of choice:	Albendazole ^{1,2}	400 mg PO once	400 mg PO once
Or	Mebendazole	100 mg PO bid × 3 d	100 mg PO bid × 3 d
Or	Endoscopic removal		

Ancylostoma Duodenale

See [Hookworm](#)

1. Not FDA approved for this indication.

2. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

Angiostrongyliasis (*Angiostrongylus cantonensis*, *Angiostrongylus costaricensis*)

Drug of choice: *A. cantonensis* causes predominantly neurotropic disease.¹ *A. costaricensis* causes gastrointestinal disease. Most patients infected with either species have a self-limited course and recover completely. Analgesics, corticosteroids, and periodic removal of cerebrospinal fluid can relieve symptoms from increased intracranial pressure.² Treatment of *A. cantonensis* is controversial and varies across endemic areas.³ No antihelminthic drug is proven to be effective, and some patients have worsened with therapy. Mebendazole or albendazole each with or without a corticosteroid appear to shorten the course of infection.⁴ Ocular angiostrongyliasis is managed by early and complete surgical removal of larva.⁵

2. Ramirez-Avila L, et al. *Clin Infect Dis.* 2009;48:322.

3. Diao Z, et al. *Emerg Infect Dis.* 2011;17:e1.

4. Sawanyawisuth K, Sawanyawisuth K. *Trans R Soc Trop Med Hyg.* 2008;102:990; Chotmongkol V, et al. *Am J Trop Med Hyg.* 2009;81:443.

5. Diao Z, et al. *Trop Doctor.* 2011;41:76.

Anisakiasis (*Anisakis* spp.)

Drug	Adult Dosage	Pediatric Dosage
Treatment of choice ¹ :	Surgical or endoscopic removal	

1. Gastric anisakiasis can usually be diagnosed and treated by endoscopic removal of the worm (Hochberg NS, Hamer DH. *Clin Infect Dis.* 2010;51:806). Enteric anisakiasis is more difficult to diagnose; capsule or double-balloon endoscopy has been used (Yasunaga H, et al. *Am J Trop Med Hyg.* 2010;83:104; Nakaji K. *Intern Med.* 2009;48:573). Disease can be managed without worm removal as the worms eventually die. Surgery may be needed in the event of intestinal obstruction or peritonitis (Repiso Ortega A, et al. *Gastroenterol Hepatol.* 2003;26:341). Successful treatment of anisakiasis with albendazole 400 mg PO bid × 3–5 d has been reported, but diagnosis was presumptive (Moore DA, et al. *Lancet.* 2002;360:54; Pacios E, et al. *Clin Infect Dis.* 2005;41:1825).

Ascariasis (*Ascaris lumbricoides*, Roundworm)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice ¹ :	Albendazole ^{2,3}	400 mg PO once	400 mg PO once
Or	Mebendazole	100 mg bid PO × 3 d or 500 mg once	100 mg PO bid × 3 d or 500 mg once
Or	Ivermectin ^{2,4}	150–200 µg/kg PO once	150–200 µg/kg PO once

1. Nitazoxanide may be effective against a variety of protozoan and helminth infections (Bobak DA, *Curr Infect Dis Rep.* 2006;8:91; Diaz E, et al. *Am J Trop Med Hyg.* 2003;68:384). It is effective against mild to moderate amebiasis, 500 mg bid × 3 d (Rossignol JF, et al. *Trans R Soc Trop Med Hyg.* 2007;101:1025; Escobedo AE, et al. *Arch Dis Child.* 2009;94:478). It is FDA approved only for treatment of diarrhea caused by *Giardia* or *Cryptosporidium* (*Med Lett Drugs Ther.* 2003;45:29). Nitazoxanide is available in 500-mg tablets and an oral suspension; it should be taken with food.

2. Not FDA approved for this indication.

3. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

4. Gonzalez P, et al. *Curr Pharm Biotechnol.* 2012;13:1103. Safety of ivermectin in young children (<15 kg) and pregnant women remains to be established; animal studies have shown adverse effects on the fetus (el-Ashmawy IM, et al. *Res Vet Sci.* 2011;90:116). Taking ivermectin with a meal increases its bioavailability (Guzzo CA, et al. *J Clin Pharmacol.* 2002;42:1122).

Babesiosis

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice ¹ :	Atovaquone ^{2,3}	750 mg PO bid × 7–10 d	40 mg/kg/d PO in 2 doses × 7–10 d
Plus	Azithromycin ²	500–1000 mg PO on day 1, then 250–500 mg PO on day 2–10	10 mg/kg (max 500 mg/dose) PO on day 1, then 5 mg/kg/d (max 250 mg dose) PO on day 2–10
Or	Clindamycin ^{2,4}	300–600 mg IV qid or 600 mg PO tid × 7–10 d	20–40 mg/kg/d (max 600 mg/dose) IV or PO in 3 or 4 doses × 7–10 d
Plus	Quinine ^{2,5}	650 mg PO tid or qid × 7–10 d	24 mg/kg/d (max 600 mg/dose) PO in 3 doses × 7–10 d

1. *Babesia microti* is the most common cause of human babesiosis in the United States (Vannier E, Krause PJ. *N Engl J Med.* 2012;366:2397), but disease caused by *B. duncani* or *B. divergens*-like organisms also has been documented (Persing DH, et al. *N Engl J Med.* 1995;332:298; Herwaldt B, et al. *Ann Intern Med.* 1996;124:643). In Europe, most cases have been attributed to *B. divergens* whereas a few have been caused by *B. venatorum* or *B. microti* (Herwaldt BL, et al. *Emerg Infect Dis.* 2003;9:942; Hunfeldt KP, et al. *Int J Parasitol.* 2008;38:1219). *B. microti*-like organisms have been identified as etiologic agents in cases reported from Japan and Taiwan. Concurrent babesiosis, Lyme disease, and/or human granulocytic anaplasmosis may occur (Thompson C, et al. *Clin Infect Dis.* 2001;33:676). Symptoms of *B. microti* infection typically are mild to moderate and are treated with atovaquone plus azithromycin (Krause PJ, et al. *N Engl J Med.* 2000;343:1454). Clindamycin plus quinine is recommended for severe symptoms with *B. microti* infection and for all *B. divergens* infections (Wormser GP, et al. *Clin Infect Dis.* 2006;43:1089; Vannier E, Krause PJ. *N Engl J Med.* 2012;366:2397). Clindamycin plus quinine is also the treatment of choice for infections caused by *B. duncani*, *B. divergens*-like organisms, or *B. venatorum*. Exchange transfusion should be considered for severely ill patients and those with high (>10%) parasitemia or pulmonary, renal, or hepatic compromise when infection is caused by *B. microti* and is recommended for cases of *B. divergens* infection. Highly immunosuppressed patients should be treated for a minimum of 6 weeks and at least 2 weeks past the last positive smear (Krause PJ, et al. *Clin Infect Dis.* 2008;46:370). High doses of azithromycin (600–1000 mg) have been used in combination with atovaquone for the treatment of immunocompromised patients (Weiss LM, et al. *N Engl J Med.* 2001;344:773). Resistance to atovaquone plus azithromycin has been reported in immunocompromised patients treated with a single subcurative course of this regimen (Wormser GP, et al. *Clin Infect Dis.* 2010; 50:381).

2. Not FDA approved for this indication.

3. Atovaquone is available in an oral suspension that should be taken with a meal to increase absorption.

4. Oral clindamycin should be taken with a full glass of water to minimize esophageal ulceration.

5. Quinine should be taken with or after a meal to decrease gastrointestinal adverse effects.

Balamuthia mandrillarisSee [Amebic Meningoencephalitis, Primary](#)**Balantidiasis (*Balantidium coli*)**

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	Tetracycline ^{1,2}	500 mg PO qid × 10 d	40 mg/kg/d (max. 2 g) PO in 4 doses × 10 d
Alternative:	Metronidazole ¹	500–750 mg PO tid × 5 d	35–50 mg/kg/d PO in 3 doses × 5 d
Or	Iodoquinol ^{1,3}	650 mg PO tid × 20 d	30–40 mg/kg/d (max 2 g) PO in 3 doses × 20 d

1. Not FDA approved for this indication.

2. Use of tetracyclines is contraindicated in pregnancy and in children <8 years. Tetracycline should be taken 1 hour before or 2 hours after meals and/or dairy products.

3. Iodoquinol should be taken after meals.

Baylisascariasis (*Baylisascaris procyonis*)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	The combination of albendazole 37 mg/kg/d PO and high-dose steroids has been used successfully. ^{1,2} Albendazole 25 mg/kg/d PO × 20 d started as soon as possible (up to 3 d after possible infection) might prevent clinical disease and is recommended for children with known exposure (ingestion of raccoon stool or contaminated soil). ³ Mebendazole, levamisole or ivermectin could be tried if albendazole is not available. Ocular baylisascariasis has been treated successfully using laser photocoagulation therapy to destroy the intraretinal larvae. ⁴		

1. Peters JM, et al. *Pediatrics*. 2012;129:e806.2. Haider S, *Emerg Infect Dis*. 2012;18:347.3. Murray WJ, Kazacos KR. *Clin Infect Dis*. 2004;39:1484.4. Garcia CA, et al. *Eye (Lond)*. 2004;18:624.***Blastocystis* spp.**

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	Clinical significance of these organisms is controversial. ¹ Treatment options include metronidazole 750 mg PO tid × 10 d, trimethoprim/sulfamethoxazole 1 DS tab PO bid × 7 d or iodoquinol 650 mg PO tid × 20 d. ² Metronidazole resistance may be common in some areas. ³ Nitazoxanide has been effective in clearing organisms and improving symptoms. ⁴		

1. Poirier P, et al. *PLoS Pathogens*. 2012;8:e1002545.2. Tan KS, *Clin Microbiol Rev*. 2008;21:639.3. Yakoob J, et al. *Br J Biomed Sci*. 2004;61:75.4. Diaz E, et al. *Am J Trop Med Hyg*. 2003;68:384; Rossignol JF. *Clin Gastroenterol Hepatol*. 2005;3:987.**Capillariasis (*Capillaria philippinensis*)**

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	Mebendazole ¹	200 mg PO bid × 20 d	200 mg PO bid × 20 d
Alternative:	Albendazole ^{1,2}	400 mg PO daily × 10 d	400 mg PO daily × 10 d

1. Not FDA approved for this indication.

2. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

Chagas' DiseaseSee [Trypanosomiasis](#)***Clonorchis sinensis***See [Fluke](#)

Cryptosporidiosis (*Cryptosporidium*)

	Drug	Adult Dosage	Pediatric Dosage
Immunocompetent			
Drug of choice:	Nitazoxanide ¹	500 mg PO bid × 3 d	1–3 y: 100 mg PO bid × 3 d 4–11 y: 200 mg PO bid × 3 d >12 y: 500 mg PO bid × 3 d
Immunocompromised			
Drug of choice:	No drug has proven efficacy in cryptosporidiosis in immunosuppressed patients. ² For HIV-infected patients, potent antiretroviral therapy is the mainstay of treatment. Nitazoxanide (treatment duration of 5–21 d), ³ paromomycin, or a combination of paromomycin and azithromycin may be tried to decrease diarrhea and recalcitrant malabsorption of antimicrobial drugs, which can occur with chronic cryptosporidiosis. ⁴		

1. Nitazoxanide may be effective against a variety of protozoan and helminth infections (Bobak DA. *Curr Infect Dis Rep*. 2006;8:91; Diaz E, et al. *Am J Trop Med Hyg*. 2003;68:384). It is effective against mild to moderate amebiasis, 500 mg bid × 3 d (Rossignol JF, et al. *Trans R Soc Trop Med Hyg*. 2007;101:1025; Escobedo AA, et al. *Arch Dis Child*. 2009;94:478), but perhaps less so than metronidazole (Becker S, et al. *Am J Trop Med Hyg*. 2011;84:581). Nitazoxanide is FDA approved only for treatment of diarrhea caused by *Giardia* or *Cryptosporidium* (*Med Lett Drugs Ther*. 2003;45:29). It is available in 500-mg tablets and an oral suspension and should be taken with food.

2. Leitch GJ, He Q. *J Biomed Res*. 2012;25:1.

3. Krause I, et al. *Pediatr Infect Dis J*. 2012;31:1135.

Cutaneous Larva Migrans (Creeping Eruption, Dog and Cat Hookworm)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice ¹ :	Albendazole ^{2,3}	400 mg PO daily × 3 d	400 mg PO daily × 3 d
Or	Ivermectin ^{2,4}	200 µg/kg PO daily × 1–2 d	200 µg/kg PO daily × 1–2 d

1. Heukelbach J, Feldmeier H. *Lancet Infect Dis*. 2008;8:302; Bowman DD, et al. *Trends Parasitol*. 2012;26:162.

2. Not FDA approved for this indication.

3. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

4. Gonzalez P, et al. *Curr Pharm Biotechnol*. 2012;13:1103. Safety of ivermectin in young children (<15 kg) and pregnant women remains to be established; animal studies have shown adverse effects on the fetus (el-Ashmawy IM, et al. *Res Vet Sci*. 2011;90:116). Taking ivermectin with a meal increases its bioavailability (Guzzo CA, et al. *J Clin Pharmacol*. 2002;42:1122).

Cyclosporiasis (*Cyclospora cayetanensis*)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice ¹ :	Trimethoprim/sulfamethoxazole ²	TMP 160 mg/SMX 800 mg (1 double-strength tab) PO bid × 7–10 d	TMP 10 mg/kg/SMX 50 mg/kg/d PO in 2 doses × 7–10 d
Alternative:	Ciprofloxacin ²	500 mg PO bid × 7 d	—

1. Ortega YR, Sanchez S. *Clin Microbiol Rev*. 2010;23:218. In one study of HIV-infected patients with *Cyclospora* infection, ciprofloxacin treatment led to resolution in 87% of patients compared to 100% with TMP/SMX (Verdier RI, et al. *Ann Intern Med*. 2000;132:885). HIV-infected patients may need higher dosage and long-term maintenance. Nitazoxanide (see also footnote 3) has also been used in a few patients, some of whom were sulfa allergic (Zimmer SM, et al. *Clin Infect Dis*. 2007; 44:466; Diaz E, et al. *Am J Trop Med Hyg*. 2003;68:384).

2. Not FDA approved for this indication.

3. Nitazoxanide may be effective against a variety of protozoan and helminth infections (Bobak DA, *Curr Infect Dis Rep*. 2006;8:91; Diaz E, et al. *Am J Trop Med Hyg*. 2003;68:384). It is effective against mild to moderate amebiasis, 500 mg bid × 3 d (Rossignol JF, et al. *Trans R Soc Trop Med Hyg*. 2007;101:1025; Escobedo AA, et al. *Arch Dis Child*. 2009;94:478), but perhaps less so than metronidazole (Becker S, et al. *Am J Trop Hyg*. 2011;84:581). Nitazoxanide is FDA approved only for treatment of diarrhea caused by *Giardia* or *Cryptosporidium* (*Med Lett Drugs Ther*. 2003;45:29). It is available in 500-mg tablets and an oral suspension and should be taken with food.

Cysticercosis

See [Tapeworm](#)

Diphyllobothrium Latum

See [Tapeworm](#)

Cystoisosporiasis (*Cystoisospora belli*, Formerly Known as *Isospora*)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice ¹ :	Trimethoprim-sulfamethoxazole (TMP-SMX) ²	TMP 160 mg/SMX 800 mg (1 double-strength tab) PO bid × 10 d	TMP 10 mg/kg/d/SMX 50 mg/kg/d PO in 2 doses × 10 d

1. *Isospora belli* has been renamed and included in the *Cystoisospora* genus. Usually a self-limited illness in immunocompetent patients. Immunosuppressed patients may need higher doses and longer duration (TMP-SMX qid for up to 3 to 4 wk (*Morbid Mortal Wkly Rep*. 2009;58 RR4:1). They may also require secondary prophylaxis (TMP-SMX DS 3 times/wk). In sulfa-allergic patients, pyrimethamine 50–75 mg daily in divided doses (plus leucovorin 10–25 mg/d) has been effective (Weiss LM, et al. *Ann Intern Med*. 1988;109:474).

2. Not FDA approved for this indication.

***Dientamoeba fragilis*¹**

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice ² :	Paromomycin ^{4,5}	25–35 mg/kg/d PO in 3 doses × 7 d	25–35 mg/kg/d PO in 3 doses × 7 d
Or	Iodoquinol ^{3,4}	650 mg PO tid × 20 d	30–40 mg/kg/d (max. 2 g) PO in 3 doses × 20 d
Or	Metronidazole ⁴	500–750 mg PO tid × 10 d	35–50 mg/kg/d PO in 3 doses × 10 d

1. Stark D, et al. *Am J Trop Med Hyg*. 2010;82:614; Vandenberg O, et al. *Pediatr Infect Dis J*. 2007;26:88; Barratt JL, et al. *Parasitology*. 2011;138:557.

2. In one study, single-dose ornidazole, a nitroimidazole similar to metronidazole that is available in Europe, was effective and better tolerated than 5 days of metronidazole (Kurt O. *Clin Microbiol Infect*. 2008;14:601).

3. Iodoquinol should be taken after meals.

4. Not FDA approved for this indication.

5. Paromomycin should be taken with a meal.

***Dracunculus medinensis* (Guinea Worm)**

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	No drug is curative against <i>Dracunculus</i> . A program for monitoring local sources of drinking water to eliminate transmission has dramatically decreased the number of cases worldwide. The treatment of choice is slow extraction of worm combined with wound care and pain management. ¹		

1. *MMWR Morbid Mortal Wkly Rep*. 2011;60:1450.

Echinococcus

See [Tapeworm](#)

Entamoeba histolytica

See [Amebiasis](#)

***Enterobius vermicularis* (Pinworm)**

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice ¹ :	Albendazole ^{2,3}	400 mg PO once; repeat in 2 wk	400 mg PO once; repeat in 2 wk
Or	Mebendazole	100 mg PO once; repeat in 2 wk	100 mg PO once; repeat in 2 wk
Or	Pyrantel pamoate ⁴	11 mg/kg base PO once (max 1 g); repeat in 2 wk	11 mg/kg base PO once (max 1 g); repeat in 2 wk

1. Since family members are usually infected, treatment of the entire household is recommended; retreatment after 14–21 d may be needed.

2. Not FDA approved for this indication.

3. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

4. Available without a prescription. Pyrantel pamoate suspension can be mixed with milk or fruit juice.

Fasciola hepatica

See [Fluke](#)

Filariasis^{1,2}

Drug		Adult Dosage	Pediatric Dosage
<i>Wuchereria bancrofti</i>, <i>Brugia malayi</i>, <i>Brugia timori</i>			
Drug of choice ³ :	Diethylcarbamazine ^{4,5}	6 mg/kg/d PO in 3 doses × 1 or 12 d ⁶	6 mg/kg/d PO in 3 doses × 1 or 12 d ⁶
<i>Loa loa</i>			
Drug of choice ⁷ :	Diethylcarbamazine ^{4,5}	9 mg/kg/d PO in 3 doses × 21 d ⁶	9 mg/kg/d PO in 3 doses × 21 d ⁶
<i>Mansonella ozzardi</i>			
Drug of choice:	See footnote 8		
<i>Mansonella perstans</i>			
Drug of choice:	See footnote 9		
<i>Mansonella streptocerca</i>			
Drug of choice ¹⁰ :	Diethylcarbamazine ^{4,5}	6 mg/kg/d PO in 3 doses × 12 d ⁶	6 mg/kg/d PO in 3 doses × 12 d ⁶
Or	Ivermectin ^{5,11}	150 µg/kg PO once	150 µg/kg PO once
Tropical Pulmonary Eosinophilia¹²			
Drug of choice:	Diethylcarbamazine ^{4,5}	6 mg/kg/d in 3 doses × 12–21 d ⁶	6 mg/kg/d in 3 doses × 12–21 d ⁶
<i>Onchocerca volvulus</i> (River Blindness)			
Drug of choice:	Ivermectin ^{11,13}	150 µg/kg PO once, repeated every 6–12 mo until asymptomatic	150 µg/kg PO once, repeated every 6–12 mo until asymptomatic

1. Antihistamines or corticosteroids may be required to decrease allergic reactions to components of disintegrating microfilariae that result from treatment, especially in infection caused by *Loa loa*.

2. Endosymbiotic *Wolbachia* bacteria, which are present in most human filariae except *Loa loa*, are essential to filarial growth, development, embryogenesis and survival and represent an additional target for therapy. Doxycycline 100 or 200 mg/d PO × 6–8 wk in lymphatic filariasis, onchocerciasis, and *Mansonella perstans* has resulted in substantial loss of *Wolbachia* and decrease in both micro- and macrofilariae (Bockarie MJ, et al. *Expert Rev Anti Infect Ther*. 2009;7:595; Hoerauf A. *Curr Opin Infect Dis*. 2008;21:673; Coulbaly YI, et al. *N Engl J Med*. 2009;361:1448). Use of tetracyclines is contraindicated in pregnancy and in children <8 y.

3. Most symptoms are caused by the adult worm. A single-dose combination of albendazole (400 mg PO) with either ivermectin (200 µg/kg PO) or diethylcarbamazine (6 mg/kg PO) is effective for reduction or suppression of *W. bancrofti* microfilaria; none of these drug combinations kills all the adult worms (Taylor MJ, et al. *Lancet*. 2010;376:1175).

4. Diethylcarbamazine is available from the CDC [(407) 718-4745; email: parasites@cdc.gov].

5. Not FDA approved for this indication.

6. Multidose regimens have been shown to provide more rapid reduction in microfilaria than single-dose diethylcarbamazine, but microfilaria levels are similar 6–12 months after treatment (Andrade LD, et al. *Trans R Soc Trop Med Hyg*. 1995;89:319; Simonsen PE, et al. *Am J Trop Med Hyg*. 1995;53:267). A single dose of 6 mg/kg is used in endemic areas for mass treatment, but there are no studies directly comparing the efficacy of the single-dose regimen to a 12-day course. One review concluded that the 12-day regimen did not have a higher macrofilaricidal effect than single dose (Hoerauf A. *Curr Opin Infect Dis*. 2008;21:673; Figueredo-Silva J, et al. *Trans R Soc Trop Med Hyg*. 1996;90:192; Noroes J, et al. *Trans R Soc Trop Med Hyg*. 1997;91:78). For patients with microfilaria in the blood, some *Medical Letter* consultants recommend starting with a lower dosage and scaling up: day 1: 50 mg; day 2: 50 mg tid; day 3: 100 mg tid; day 4–14: 6 mg/kg/d in 3 doses (for *Loa loa* day 4–14: 9 mg/kg/d in 3 doses). Diethylcarbamazine should not be used for treatment of *Onchocerca volvulus* due to the risk of increased ocular side effects (including blindness) associated with rapid killing of the worms. It should be used cautiously in geographic regions where *O. volvulus* coexists with other filariae. See also footnote 13.

7. Bossinesq M. *J Travel Med*. 2012;19:140. In heavy infections with *Loa loa*, rapid killing of microfilariae can provoke encephalopathy. Apheresis has been reported to be effective in lowering microfilarial counts in patients heavily infected with *Loa loa* (Ottesen EA. *Infect Dis Clin North Am*. 1993;7:619). Albendazole may be useful for treatment of loiasis when diethylcarbamazine is ineffective or cannot be used, but repeated courses may be necessary (Klion AD, et al. *Clin Infect Dis*. 1999;29:680; Tabi TE, et al. *Am J Trop Med Hyg*. 2004;71:211). Ivermectin has also been used to reduce microfilaremia, but albendazole is preferred because of its slower onset of action and lower risk of precipitating encephalopathy (Klion AD, et al. *J Infect Dis*. 1993;168:202; Kombila M, et al. *Am J Trop Med Hyg*. 1998;58:458). Diethylcarbamazine, 300 mg PO once/wk, has been recommended for prevention of loiasis (Nutman TB, et al. *N Engl J Med*. 1988; 319:752).

8. Diethylcarbamazine has no effect. A single dose of ivermectin 200 µg/kg PO reduces microfilaria densities and provides both short- and long-term reductions in *M. ozzardi* microfilaremia (Gonzalez AA, et al. *W Indian Med J*. 1999;48:231). These parasites have been shown to contain *Wolbachia* which suggests doxycycline might be effective. See also footnote 2.

9. Diethylcarbamazine, mebendazole and ivermectin have not been found to be effective against *M. perstans*. Doxycycline is the drug of choice for disease acquired in West Africa (Coulbaly YI, et al. *N Engl J Med*. 2009;361:1448). Strains from Uganda appear not to have *Wolbachia* (Grobush MP, et al. *Parasitol Res*. 2003;90:405). There is no effective therapy for patients with these strains or those who cannot take doxycycline (pregnant women, young children). See also footnote 2.

10. Diethylcarbamazine is potentially curative due to activity against both adult worms and microfilariae. Geographic overlap with *Onchocerca volvulus* and inability of most labs to distinguish between the species limits its use. Ivermectin is active only against microfilariae and can lead to long-term suppression (Fischer P, et al. *J Infect Dis*. 1999;180:1403). These parasites have been shown to contain *Wolbachia* which suggests doxycycline might be effective. See also footnote 2.

11. Gonzalez P, et al. *Curr Pharm Biotechnol*. 2012;13:1103. Safety of ivermectin in young children (<15 kg) and pregnant women remains to be established; animal studies have shown adverse effects on the fetus (el-Ashmawy IM, et al. *Res Vet Sci*. 2011;90:116). Taking ivermectin with a meal increases its bioavailability (Guzzo CA, et al. *J Clin Pharmacol*. 2002;42:1122).

12. Vijayan VK. *Curr Opin Pulm Med*. 2007;13:428. Relapses occur and can be treated with a repeated course of diethylcarbamazine.

13. Diethylcarbamazine should not be used for treatment of this disease because rapid killing of the worms can lead to blindness. Periodic treatment with ivermectin (every 3–12 mo), 150 µg/kg PO, can prevent blindness due to ocular onchocerciasis (Udall DN, *Clin Infect Dis*. 2007;44:53). Skin reactions after ivermectin treatment are often reported in persons with high microfilarial skin densities. Ivermectin has been inadvertently given to pregnant women during mass treatment programs; the rates of congenital abnormalities were similar in treated and untreated women. Because of the high risk of blindness from onchocerciasis, the use of ivermectin after the first trimester is considered acceptable according to the WHO. Addition of 6–8 weeks of doxycycline to ivermectin is increasingly common. Doxycycline (100 mg/day PO for 6 weeks), alone or followed by a single 150 µg/kg PO dose of ivermectin, resulted in long-term amicrofilaridemia and elimination of *Wolbachia* species (Hoerauf A, et al. *Lancet*. 2001;357:1415; Hoerauf A, et al. *Parasitol Res*. 2009;104:437).

Fluke, Hermaphroditic			
Drug		Adult Dosage	Pediatric Dosage
<i>Clonorchis sinensis</i> (Chinese Liver Fluke)¹			
Drug of choice:	Praziquantel ²	75 mg/kg/d PO in 3 doses × 1–2 d	75 mg/kg/d PO in 3 doses × 1–2 d
Or	Albendazole ^{3,4}	10 mg/kg/d PO × 7 d	10 mg/kg/d PO × 7 d
<i>Fasciola hepatica</i> (Sheep Liver Fluke)¹			
Drug of choice ⁵ :	Triclabendazole ^{7*}	10 mg/kg PO once or twice	10 mg/kg PO once or twice
Alternative:	Bithionol [*]	30–50 mg/kg on alternate days × 10–15 doses	30–50 mg/kg on alternate days × 10–15 doses
Or	Nitazoxanide ^{3,6}	500 mg PO bid × 7 d	1–3 y: 100 mg PO bid × 7 d 4–11 y: 200 mg PO bid × 7 d >12 y: 500 mg PO bid × 7 d
<i>Fasciolopsis buski</i>, <i>Heterophyes heterophyes</i>, <i>Metagonimus yokogawai</i> (Intestinal Flukes)			
Drug of choice:	Praziquantel ^{2,3}	75 mg/kg/d PO in 3 doses × 1 d	75 mg/kg/d PO in 3 doses × 1 d
<i>Metorchis conjunctus</i> (North American Liver Fluke)			
Drug of choice:	Praziquantel ^{2,3}	75 mg/kg/d PO in 3 doses × 1 d	75 mg/kg/d PO in 3 doses × 1 d
<i>Nanophyetus salmincola</i>			
Drug of choice:	Praziquantel ^{2,3}	60 mg/kg/d PO in 3 doses × 1 d	60 mg/kg/d PO in 3 doses × 1 d
<i>Opisthorchis viverrini</i> (Southeast Asian Liver Fluke)¹			
Drug of choice:	Praziquantel ²	75 mg/kg/d PO in 3 doses × 2 d	75 mg/kg/d PO in 3 doses × 2 d
Or	Albendazole ^{3,4}	10 mg/kg/d PO × 7 d	10 mg/kg/d PO × 7 d
Paragonimiasis (<i>P. westermani</i>, <i>P. miyazaki</i>, <i>P. skrjabini</i>, <i>P. hueitungensis</i>, <i>P. heterotrema</i>, <i>P. utcerobilaterus</i>, <i>P. africanus</i>, <i>P. mexicanus</i>, <i>P. kellicotti</i>) (Lung Fluke)			
Drug of choice:	Praziquantel ^{2,3}	75 mg/kg/d PO in 3 doses × 2 d	75 mg/kg/d PO in 3 doses × 2 d
Alternative:	Triclabendazole ^{7*}	10 mg/kg PO once or twice	10 mg/kg PO once or twice
	Bithionol [*]	30–50 mg/kg on alternate days × 10–15 doses	30–50 mg/kg on alternate days × 10–15 doses

*Availability problems. See Table 241.2.

1. Marcos LA. *Curr Opin Infect Dis.* 2008;21:523; Hong ST, Fang Y. *Parasitol Int.* 2012;61:17; Keiser J, et al. *Curr Opin Infect Dis.* 2010;25:513.

2. Praziquantel should be taken with liquids during a meal.

3. Not FDA approved for this indication.

4. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

5. Unlike infections with other flukes, *Fasciola hepatica* infections may not respond to praziquantel. Triclabendazole (Egaten) appears to be safe and effective, but data are limited (Keiser J, et al. *Expert Opin Investig Drugs.* 2005;14:1513). It is available from Victoria Pharmacy, Zurich, Switzerland (www.pharmaworld.com; 011-4143-344-60-60) and should be given with food for better absorption. Nitazoxanide also appears to have efficacy in treating fascioliasis in adults and in children (Favennec L, et al. *Aliment Pharmacol Ther.* 2003;17:265; Rossignol JF, et al. *Trans R Soc Trop Med Hyg.* 1998;92:103; Kabil SM, et al. *Curr Ther Res.* 2000;61:339).

6. Nitazoxanide may be effective against a variety of protozoan and helminth infections (Bobak DA. *Curr Infect Dis Rep.* 2006;8:91; Diaz E, et al. *Am J Trop Med Hyg.* 2003;68:384). It is effective against mild to moderate amebiasis, 500 mg bid × 3 d (Rossignol JF, et al. *Trans R Soc Trop Med Hyg.* 2007;101:1025; Escobedo AE, et al. *Arch Dis Child.* 2009;94:478), but perhaps less so than metronidazole (Becker S, et al. *Am J Trop Med Hyg.* 2011;84:581). Nitazoxanide is FDA approved only for treatment of diarrhea caused by *Giardia* or *Cryptosporidium* (*Med Lett Drugs Ther.* 2003;45:29). Nitazoxanide is available in 500-mg tablets and an oral suspension and should be taken with food.

7. Keiser J, et al. *Expert Opin Investig Drugs.* 2005;14:1513. See footnote 5 for availability.

Giardiasis (<i>Giardia duodenalis</i>)			
Drug		Adult Dosage	Pediatric Dosage
Drug of choice:	Tinidazole ¹	2 g PO once	≥3 y: 50 mg/kg PO once (max 2 g)
Or	Metronidazole ²	250 mg PO tid × 5–7 d	15 mg/kg/d PO in 3 doses × 5–7 d
Or	Nitazoxanide ³	500 mg PO bid × 3 d	1–3 y: 100 mg PO bid × 3 d 4–11 y: 200 mg PO bid × 3 d >12 y: 500 mg PO bid × 3 d
Alternative ⁴ :	Paromomycin ^{2,5,6}	25–35 mg/kg/d PO in 3 doses × 5–10 d	25–35 mg/kg/d PO in 3 doses × 5–10 d
Or	Furazolidone [*]	100 mg PO qid × 7–10 d	6 mg/kg/d PO in 4 doses × 7–10 d
Or	Quinacrine ^{7,8*}	100 mg PO tid × 5 d	6 mg/kg/d PO in 3 doses × 5 d (max 300 mg/d)

*Availability problems. See Table 241.2.

1. A nitroimidazole similar to metronidazole, tinidazole appears to be as effective as metronidazole and better tolerated (*Med Lett Drugs Ther.* 2004;46:70). It should be taken with food to minimize adverse GI effects. For children and patients unable to take tablets, a pharmacist can crush the tablets and mix them with cherry syrup (Humco, and others). The syrup suspension is good for 7 days at room temperature and must be shaken before use (Fung HB, Doan TL. *Clin Ther.* 2005; 27:1859). Ornidazole, a similar drug, is also used outside the United States.

2. Not FDA approved for this indication.

3. Nitazoxanide may be effective against a variety of protozoan and helminth infections (Bobak DA. *Curr Infect Dis Rep.* 2006;8:91; Diaz E, et al. *Am J Trop Med Hyg.* 2003;68:384). It is effective against mild to moderate amebiasis, 500 mg bid × 3 d (Rossignol JF, et al. *Trans R Soc Trop Med Hyg.* 2007;101:1025; Escobedo AA, et al. *Arch Dis Child.* 2009;94:478), but perhaps less so than metronidazole (Becker S, et al. *Am J Trop Med Hyg.* 2011;84:581). Nitazoxanide is FDA approved only for treatment of diarrhea caused by *Giardia* or *Cryptosporidium* (*Med Lett Drugs Ther.* 2003;45:29). It is available in 500-mg tablets and an oral suspension and should be taken with food.

4. Additional option: albendazole (400 mg/d PO × 5 d in adults and 10 mg/kg/d PO × 5 d in children) (Yereli K, et al. *Clin Microbiol Infect.* 2004;10:527; Karabay O, et al. *World J Gastroenterol.* 2004;10:1215). Refractory disease: combination therapy with tinidazole or metronidazole plus paromomycin, furazolidone, or quinacrine has been successful (Nash TE, et al. *Clin Infect Dis.* 2001;33:22; Lopez-Velez R, et al. *Am J Trop Med Hyg.* 2010;83:171). In one study, nitazoxanide was used successfully in high doses (1.5 g PO bid × 30 d) to treat a case of *Giardia* resistant to metronidazole and albendazole (Abboud P, et al. *Clin Infect Dis.* 2001;32:1792).

5. Paromomycin should be taken with a meal.

6. Poorly absorbed; may be useful for treatment of giardiasis in pregnancy.

7. Not available commercially. It may be obtained through compounding pharmacies such as Expert Compounding Pharmacy, 6744 Balboa Blvd, Lake Balboa, CA 91406 (800-247-9767) or Medical Center Pharmacy, New Haven, CT (203-688-7064). Other compounding pharmacies may be found through the National Association of Compounding Pharmacies (800-687-7850) or the Professional Compounding Centers of America (800-331-2498, www.pccarx.com).

8. Quinacrine should be taken with liquids after a meal.

Gnathostomiasis (*Gnathostoma spinigerum*)¹

	Drug	Adult Dosage	Pediatric Dosage
Treatment of choice:	Albendazole ^{2,3}	400 mg PO bid × 21 d	400 mg PO bid × 21 d
Or	Ivermectin ^{2,4}	200 µg/kg/d PO × 2 d	200 µg/kg/d PO × 2 d
Either ±	Surgical removal		

1. All patients should be treated with medication whether surgery is attempted or not. Herman JS, Chiodini PL. *Clin Microbiol Rev.* 2009;22:484; Ramirez-Avila L, et al. *Clin Infect Dis.* 2009;48:322.

2. Not FDA approved for this indication.

3. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

4. Gonzalez P, et al. *Curr Pharm Biotechnol.* 2012;13:1103. Safety of ivermectin in young children (<15 kg) and pregnant women remains to be established; animal studies have shown adverse effects on the fetus (el-Ashmawy IM, et al. *Res Vet Sci.* 2011;90:116). Taking ivermectin with a meal increases its bioavailability (Guzzo CA, et al. *J Clin Pharmacol.* 2002;42:1122).

Gongylonemiasis (*Gongylonema* spp.)¹

	Drug	Adult Dosage	Pediatric Dosage
Treatment of choice:	Surgical removal		
Or	Albendazole ^{2,3}	400 mg/d PO × 3 d	400 mg/d PO × 3 d

1. Pasuralertsakul S, et al. *Am Trop Med Parasitol.* 2008;102:455; Molavi G, et al. *J Helminth* 2006;80:425.

2. Not FDA approved for this indication.

3. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

Hookworm (*Ancylostoma duodenale*, *Necator americanus*)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	Albendazole ^{1,2}	400 mg PO once	400 mg PO once
Or	Mebendazole	100 mg PO bid × 3 d or 500 mg once	100 mg PO bid × 3 d or 500 mg once
Or	Pyrantel pamoate ^{1,3}	11 mg/kg base (max 1 g) PO daily × 3 d	11 mg/kg base (max 1 g) PO daily × 3 d

1. Not FDA approved for this indication.

2. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

3. Available without a prescription. Pyrantel pamoate suspension can be mixed with milk or fruit juice.

	Drug	Adult Dosage	Pediatric Dosage
Visceral^{2,3}			
Drug of choice:	Liposomal amphotericin B	See footnote 4	See footnote 4
Alternative:	Sodium stibo-gluconate*	20 mg antimony kg/d IV or IM × 28 d	20 mg antimony kg/d IV or IM × 28 d
Or	Meglumine antimonate*	20 mg antimony kg/d IV or IM × 28 d	20 mg antimony kg/d IV or IM × 28 d
Or	Miltefosine ^{5,6*}	2.5 mg/kg/d PO (max 150 mg/d) × 28 d	2.5 mg/kg/d PO (max 150 mg/d) × 28 d
Or	Amphotericin B ⁷	1 mg/kg IV daily × 15–20 d or every second day for 4–8 wk (total usually 15–20 mg/kg)	1 mg/kg IV daily × 15–20 d or every second day for 4–8 wk (total usually 15–20 mg/kg)
Or	Paromomycin ^{7,8*} sulfate	15 mg/kg/d IM × 21 d	15 mg/kg/d IM × 21 d
Cutaneous^{1,2,9}			
Drugs of choice:	Sodium stibo-gluconate*	20 mg antimony kg/d IV or IM × 20 d	20 mg antimony kg/d IV or IM × 20 d
OR	Meglumine antimonate*	20 mg antimony kg/d IV or IM × 20 d	20 mg antimony kg/d IV or IM × 20 d
Or	Miltefosine ^{5,10*}	2.5 mg/kg/d PO (max 150 mg/d) × 28 d	2.5 mg/kg/d PO (max 150 mg/d) × 28 d
Alternative ¹¹ :	Paromomycin ^{7,12*}	Topically 2 ×/d × 10–20 d	Topically 2 ×/d × 10–20 d
Or	Pentamidine ⁷	2–3 mg/kg IV or IM daily or every second day × 4–7 doses	2–3 mg/kg IV or IM daily or every second day × 4–7 doses
Mucosal^{1,2,13}			
Drug of choice:	Sodium stibogluconate*	20 mg antimony kg/d IV or IM × 28 d	20 mg antimony kg/d IV or IM × 28 d
Or	Meglumine antimonate*	20 mg antimony kg/d IV or IM × 28 d	20 mg antimony kg/d IV or IM × 28 d
Or	Amphotericin B ^{7,14}	0.5–1 mg/kg IV daily or every second day for 4–8 wk	0.5–1 mg/kg IV daily or every second day for 4–8 wk
Or	Miltefosine ^{5,15*}	2.5 mg/kg/d PO (max 150 mg/d) × 28 d	2.5 mg/kg/d PO (max 150 mg/d) × 28 d

*Availability problems. See Table 241.2.

1. Murray HW. *Am J Trop Med Hyg.* 2012;86:434.

2. Medical Letter reviewers recommend consultation with physicians experienced in management of this disease. To maximize effectiveness and minimize toxicity, the choice of drug, dosage, and duration of therapy should be individualized based on the region of disease acquisition, likely infecting species, number, significance and location of lesions, and host factors such as immune status (Murray HW. *Lancet.* 2005;366:1561). Some of the listed drugs and regimens are effective only against certain *Leishmania* species/strains and only in certain areas of the world (Sundar S, Chakravarty J. *Expert Opin Pharmacother.* 2013;14:53).

3. Visceral infection is most commonly due to the Old World species *L. donovani* (kala-azar) and *L. infantum* (referred to as *L. chagasi* in the New World) (van Griensven J, Diro E. *Infect Clin Dis Clin North Am.* 2012;26:309).

4. Liposomal amphotericin B is the only lipid formulation of amphotericin B FDA approved for treatment of visceral leishmaniasis, largely based on trials in patients infected with *L. infantum* (Balasegaram M, et al. *Expert Opin Emerg Drugs.* 2012;17:493). It is the treatment of choice for visceral leishmaniasis in the United States and Southern Europe and the treatment of choice for visceral disease in pregnancy. The total dose administered seems to be more important than the number of infusions or duration of therapy. The target dose for a nonimmunocompromised host is 18–21 mg/kg over 5 d. Two doses of 10 mg/kg have been used successfully in children with disease acquired in the Mediterranean (Syriopoulou V, et al. *Clin Infect Dis.* 2003;36:560). For visceral leishmaniasis acquired in the Indian subcontinent 10 mg/kg/d as a single dose or 5-d treatment with 3 mg/kg (total 15 mg/kg) has been effective (Murray HW, et al. *Lancet.* 2005;366:1561; Bern C, et al. *Clin Infect Dis.* 2006;43:917; Sundar S, et al. *N Engl J Med.* 2010;362:504). The FDA-approved dosage regimen is 3 mg/kg/d IV on days 1–5, 14, and 21 and for immunocompromised patients is 4 mg/kg on days 1–5, 10, 17, 24, 31, and 38. The relapse rate in immunocompromised patients is high; maintenance therapy (secondary prevention) is generally given indicated, but there is no consensus on dosage and duration.

5. Dorlo TP, et al. *J Antimicrob Chemother.* 2012;67:2576. Miltefosine (Impavido) is manufactured in 10- or 50-mg capsules by Paladin (Canada) and is available in the United States from the manufacturer through an IND application from the FDA. The drug is contraindicated in breastfeeding and pregnant women; a negative pregnancy test before drug initiation and effective contraception during and for 4 months after treatment is recommended (Murray HW, et al. *Lancet.* 2005;366:1561).

6. Miltefosine is effective for both antimony-sensitive and -resistant *L. donovani* (Indian).

7. Not FDA approved for this indication.

8. Paromomycin IM has been effective against *Leishmania* in India and against visceral leishmaniasis in East Africa, although higher doses (20 mg/kg) or longer duration of therapy may be needed (Musa AH, et al. *PLoS Negl Trop Dis.* 2010;4:e855; Hailu A, et al. *PLoS Negl Trop Dis.* 2010;4:e709. There are insufficient data to support its use in pregnancy (Sundar S, et al. *N Engl J Med.* 2007;356:2571; Sundar S, Chakravarty J. *Expert Opin Investig Drugs.* 2008;17:787). There is limited experience in paromomycin in South America or the Mediterranean, where it has been tried as second-line combination therapy with sodium stibogluconate.

9. Cutaneous infection is most commonly due to the Old World species *L. major* and *L. tropica* and the New World species *L. mexicana*, *L. (Vianna) braziliensis*, *L. (V.) panamensis* and others.

10. Machado PR, Penna G. *Curr Opin Infect Dis.* 2012;25:141. Miltefosine has been effective in trials for treatment of cutaneous leishmaniasis due to *L. (V.) panamensis* in Bolivia and Colombia, and for *L. (V.) braziliensis* in Brazil but not for treatment of *L. (V.) braziliensis* or *L. mexicana* in Guatemala, suggesting geography as well as species affects efficacy (Soto J, et al. *Am J Trop Med Hyg.* 2008;78:210; Machado PR, et al. *PLoS Negl Trop Dis.* 2010;4:e912; Soto J, et al. *Clin Infect Dis.* 2004;38:1266; Rubiano LC, et al. *J Infect Dis.* 2012;205:684). It has also been effective for treatment of *L. major* acquired in Afghanistan and Iran (Mohebbi, et al. *Acta Trop.* 2007;103:33; van Thiel PP, et al. *Clin Infect Dis.* 50:80). For forms of disease that require long periods of treatment, such as diffuse cutaneous leishmaniasis and post kala-azar dermal leishmaniasis, miltefosine might be a useful treatment (Berman JJ. *Expert Opin Drug Metab Toxicol.* 2008;4:1209).

11. Azole drugs (fluconazole, ketoconazole, itraconazole) have been used to treat cutaneous disease, with plausible efficacy (Blum JA, Hatz CS. *J Travel Med.* 2009;16:123). For treatment of *L. major* cutaneous lesions, a study in Saudi Arabia found that oral fluconazole, 200 mg once/d × 6 wk appeared to modestly accelerate the healing process (Alrajhi AA, et al. *N Engl J Med.* 2002;346:891). Fluconazole 8 mg/kg/d PO × 4–6 wk may have efficacy against *L. braziliensis* (Sousa AQ, et al. *Clin Infect Dis.* 2011;53:693). Intraleisional injections of sodium stibogluconate or topical paromomycin are also used for uncomplicated lesions when subsequent mucosal leishmaniasis is unlikely (Soto J, et al. *Clin Infect Dis.* 2013;56:1255). Ketoconazole 600 mg/day PO × 28–30 d has been effective against *L. major*, *L. panamensis*, and *L. mexicana*. Studies with liposomal amphotericin are limited; the FDA total approved dose of 21 mg/kg may be effective (Wortmann G, et al. *Am J Trop Hyg.* 2010;83:1028). Thermotherapy may be an option for some cases of cutaneous *L. tropica* infection (Reithinger R, et al. *Clin Infect Dis.* 2005;40:1148). A device that generates focused and controlled heating of the skin is being marketed (ThermoMed; ThermoSurgery Technologies Inc., Phoenix, AZ, 602-264-7300; www.thermosurgery.com). In a few studies, localized thermal heat was as effective as multiple doses of sodium stibogluconate or meglumine antimonate for up to 18 months with less toxicity (Safi N, et al. *Mil Med.* 2012;177:345; Lopez L, et al. *Trials.* 2012;13:58; Bumb RA, et al. *Br J Dermatol.* 2013;Jan 8).

12. Topical paromomycin should be used only in geographic regions where cutaneous leishmaniasis species have low potential for mucosal spread. A formulation of 15% paromomycin/12% methylbenzethonium chloride (Leshcutan) in soft white paraffin for topical use has been reported to be partially effective against cutaneous leishmaniasis due to *L. major* in Israel and Tunisia and *L. mexicana* and *L. (V.) braziliensis* in Guatemala, where mucosal spread is very rare (Arana BA, et al. *Am J Trop Med Hyg.* 2001;65:466; Kim DH, et al. *PLoS Negl Trop Dis.* 2009;3:e381; Ben Salah A, et al. *N Engl J Med.* 2013;368:524). The methylbenzethonium is irritating to the skin; lesions may worsen before they improve.

13. Mucosal infection (espundia) is most commonly due to New World species *L. (V.) braziliensis*, *L. (V.) panamensis*, or *L. (V.) guyanensis*.

14. Liposomal amphotericin 20–35 mg/kg divided in 3–5 doses may be active for mucosal disease (Amato VS, et al. *Am J Trop Med Hyg.* 2011;85:818).

15. Miltefosine has been effective for mucosal leishmaniasis due to *L. (V.) braziliensis* in Bolivia (Soto J, et al. *Clin Infect Dis.* 2007;44:350; Soto J, et al. *Am J Trop Med Hyg.* 2009;81:387).

Lice (*Pediculus humanus*, *P. capitis*, *Phthirus pubis*)¹

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	Pyrethrins with piperonyl butoxide ²	Topically, 2 × at least 7 d apart	Topically, 2 × at least 7 d apart
<i>Or</i>	0.5% ivermectin lotion ³	Topically, once	Topically, once
<i>Or</i>	0.9% spinosad susp ⁴	Topically, 2 × at least 7 d apart	Topically, 2 × at least 7 d apart
<i>Or</i>	1% permethrin ²	Topically, 2 × at least 7 d apart	Topically, 2 × at least 7 d apart
<i>Or</i>	5% benzyl alcohol lotion ⁵	Topically, 2 × at least 7 d apart	Topically, 2 × at least 7 d apart
<i>Or</i>	0.5% malathion ⁶	Topically, 2 × at least 7 d apart	Topically, 2 × at least 7 d apart
Alternative:	Ivermectin ^{7,8,9}	200 or 400 µg/kg PO	>15 kg: 200 or 400 µg/kg PO

1. Pediculocides should not be used for infestations of the eyelashes. Such infestations are treated with petrolatum ointment applied 2–4 ×/d × 8–10 d. For pubic lice, treat with 1% permethrin, pyrethrins with piperonyl butoxide, or ivermectin.

2. Permethrin and pyrethrin are pediculocidal; retreatment in 7–10 d is needed to eradicate the infestation. Some lice are resistant to pyrethrins and permethrin (Meinking TL, et al. *Arch Dermatol.* 2002;138:220). *Medical Letter* consultants prefer pyrethrin products with a benzyl alcohol vehicle. Pyrethrins with piperonyl butoxide are recommended for use in children ≥2 y; permethrin for children ≥2 mo.

3. Not ovicidal, but lice that hatch from treated eggs die within 48 hours after hatching. Recommended for use in children ≥6 mo (*Med Lett Drugs Ther.* 2012;54:61; Pariser DM, et al. *N Engl J Med.* 2012;367:1687).

4. Not ovicidal, but causes neuronal excitation in insects leading to paralysis and death. The formulation also includes benzyl alcohol, which is pediculocidal. Two applications 7 days apart are needed. Recommended for children ≥4 y (*Med Lett Drugs Ther.* 2011;53:50).

5. Benzyl alcohol prevents lice from closing their respiratory spiracles and the lotion vehicle then obstructs their airway, causing them to asphyxiate. It is not ovicidal. Two applications at least 7 d apart are needed. Recommended for use in children ≥6 mo. Resistance, which is a problem with other drugs, is unlikely to develop (*Med Lett Drugs Ther.* 2009;51:57).

6. Malathion is both ovicidal and pediculocidal; 2 applications at least 7 d apart are generally necessary to kill all lice and nits. Recommended for children ≥6 y.

7. Not FDA approved for this indication.

8. Gonzalez P, et al. *Curr Pharm Biotechnol.* 2012;13:1103. Safety of ivermectin in young children (<15 kg) and pregnant women remains to be established; animal studies have shown adverse effects on the fetus (el-Ashmawy Im, et al. *Res Vet Sci.* 2011;90:116). Taking ivermectin with a meal increases its bioavailability (Guzzo CA, et al. *J Clin Pharmacol.* 2002;42:1122).

9. Ivermectin is pediculocidal, but not ovicidal; more than one dose is generally necessary to eradicate the infestation (Jones KN, English JC 3d. *Clin Infect Dis.* 2003;36:1355). The number of doses and interval between doses has not been established; animal studies have shown adverse effects on the fetus (el-Ashmawy IM, et al. *Res Vet Sci.* 2011;90:116). In one study of treatment of head lice, 2 doses of ivermectin (400 µg/kg) 7 days apart were more effective than treatment with topical malathion (Chosidow O, et al. *N Engl J Med.* 2010;362:896). In one study of treatment of body lice, a regimen of 3 doses of ivermectin (12 mg each) administered at 7-d intervals was effective (Fouault C, et al. *J Infect Dis.* 2006;193:474).

Loa loa

See [Filariasis](#)

Malaria, Treatment (*Plasmodium falciparum*,¹ *P. vivax*,² *P. ovale*, *P. malariae*,³ and *P. knowlesi*)⁴

	Drug	Adult Dosage	Pediatric Dosage
Oral (Uncomplicated or Mild Infection)⁵			
<i>P. falciparum</i> or Unidentified Species⁶ Acquired in Areas of Chloroquine-Resistant <i>P. falciparum</i>⁷			
Drug of choice:	Atovaquone/proguanil ⁷	4 adult tabs PO once/d or 2 adult tabs PO bid × 3 d ⁸	<5 kg: not indicated 5–8 kg: 2 peds tabs PO once/d × 3 d 9–10 kg: 3 peds tabs PO once/d × 3 d 11–20 kg: 1 adult tab PO once/d × 3 d 21–30 kg: 2 adult tabs PO once/d × 3 d 31–40 kg: 3 adult tabs PO once/d × 3 d >40 kg: 4 adult tabs PO once/d × 3 d ⁸

*Availability problems. See [table 241.2](#).

1. Chloroquine-resistant *P. falciparum* occurs in all malarious areas except Central America (including Panama north and west of the Canal Zone), Mexico, Haiti, the Dominican Republic, Paraguay, northern Argentina, North and South Korea, Georgia, Armenia, most of rural China, and some countries in the Middle East (chloroquine resistance has been reported in Yemen, Saudi Arabia, and Iran). For treatment of multiple-drug-resistant *P. falciparum* in Southeast Asia, especially the greater Mekong region that includes Myanmar, Thailand, Cambodia, and Vietnam, where mefloquine resistance is frequent, atovaquone/proguanil, quinine plus either doxycycline or clindamycin, or artemether/lumefantrine may be used.

2. Chloroquine-resistant *P. vivax* is a significant problem in Papua-New Guinea and Indonesia. There are also reports of resistance from Myanmar, Vietnam, Korea, India, the Solomon Islands, Vanuatu, Indonesia, Guyana, Brazil, Colombia, and Peru (Baird JK. *Clin Microbiol Rev.* 2009;22:508).

3. Chloroquine-resistant *P. malariae* has been reported from Sumatra (Maguire JD, et al. *Lancet.* 2002;360:58).

4. Human infection with the simian species, *P. knowlesi*, has been reported in Malaysia where it was initially misdiagnosed as *P. malariae*. Additional cases have been reported from Thailand, Myanmar, Singapore, the Thai-Burma border, and the Philippines (Cox-Singh J, et al. *Clin Infect Dis.* 2008;46:165; *MMWR* 2009;58:229). Treatment with the usual antimalarials, such as chloroquine and atovaquone/proguanil, appears to be effective. In cases of severe infection, IV artesunate combined with oral artemether/lumefantrine or artesunate/mefloquine has been used successfully (Barber BE, et al. *Clin Infect Dis.* 2013;56:383).

5. Uncomplicated or mild malaria may be treated with oral drugs. Severe malaria (e.g., impaired consciousness, parasitemia >5%, shock) should be treated with parenteral drugs (Griffin KS, et al. *JAMA.* 2007;297:2264). Malaria breakthrough infection in a patient on prophylaxis should be treated with a different drug than the drug taken for prophylaxis.

6. Primaquine is given as part of primary treatment to prevent relapse after infection with *P. vivax* or *P. ovale*. Vivax malaria is a potentially more dangerous infection than previously thought (Baird JK, et al. *Microbiol Rev.* 2013; 26:36). See also footnote 20.

7. Atovaquone/proguanil is available as a fixed-dose combination tablet: adult tablets (Malarone; atovaquone 250 mg/proguanil 100 mg) and pediatric tablets (Malarone pediatric; atovaquone 62.5 mg/proguanil 25 mg). To enhance absorption and reduce nausea and vomiting, it should be taken with food or a milky drink. Safety in pregnancy is unknown and use is generally not recommended. In a few small studies outcomes were normal in women treated with the combination in the 2nd and 3rd trimester (Pasternak B, et al. *Arch Intern Med.* 2011;171:259; Boggild AK, et al. *Am J Trop Med Hyg.* 2007;76:208). The drug should not be given to patients with severe renal impairment (creatinine clearance <30 mL/min). There have been isolated case reports of resistance in *P. falciparum* in Africa, but *Medical Letter* consultants do not believe there is a high risk for acquisition of Malarone-resistant disease (Schwartz E, et al. *Clin Infect Dis.* 2003;37:450; Farnert A, et al. *BMJ.* 2003;326:628; Kuhn S, et al. *Am J Trop Med Hyg.* 2005;72:407; Happi CT, et al. *Malaria J.* 2006;5:82).

8. Although approved for once-daily dosing, *Medical Letter* consultants usually divide the dose in two to decrease nausea and vomiting.

Malaria, Treatment (*Plasmodium falciparum*,¹ *P. vivax*,² *P. ovale*, *P. malariae*,³ and *P. knowlesi*⁴)—cont'd

	Drug	Adult Dosage	Pediatric Dosage
Or	Artemether/ lumefantrine ^{9,10}	6 doses over 3 d (4 tabs/dose at 0, 8, 24, 36, 48 and 60 h)	6 doses over 3 d at same intervals as adults: 5–15 kg: 1 tab/dose ≥15–25 kg: 2 tabs/dose ≥25–35 kg: 3 tabs/dose ≥35 kg: 4 tabs/dose

	Mefloquine ¹⁸	750 mg PO followed 12 h later by 500 mg	15 mg/kg PO followed 12 h later by 10 mg/kg
Either plus	Primaquine phosphate ^{6,20}	30 mg base/d PO × 14 d	0.5 mg/kg/d PO × 14 d
<i>Plasmodium</i> spp. in Areas Without Chloroquine Resistance^{1–4}			
Drug of choice:	Chloroquine phosphate ^{6,23}	1 g (600 mg base) PO, then 500 mg (300 mg base) 6 h later, then 500 mg (300 mg base) at 24 and 48 h	10 mg base/kg (max 600 mg base) PO, then 5 mg base/kg 6 h later, then 5 mg base/ kg at 24 and 48 h
Or	Regimen used for chloroquine-resistant species listed above		

9. The artemisinin-derivatives, artemether and artesunate, are both frequently used globally in combination regimens to treat malaria. Both are available in oral, parenteral and rectal formulations, but manufacturing standards are not consistent (Karunajeewa HA, et al. *JAMA*. 2007;297:2381; Ashley EA, White NJ. *Curr Opin Infect Dis*. 2005;18:531). Based on the few studies available, artemesinins have been relatively safe during pregnancy (Adam I, et al. *Am Trop Med Parasitol*. 2009;103:205), but some experts would not prescribe them in the 1st trimester (Clark RL. *Reprod Toxicol*. 2009;28:285; Manyando C, et al. *Malaria J*. 2012;11:141).

10. Artemether/lumefantrine is available as a fixed-dose combination tablet (Coartem in the United States and in countries with endemic malaria, Riamet in Europe and countries without endemic malaria); each tablet contains artemether 20 mg and lumefantrine 120 mg. It is FDA approved for treatment of uncomplicated malaria and should not be used for severe infection or for prophylaxis. The tablets should be taken with fatty food (tablets may be crushed, mixed with 1–2 tsp water, and taken with milk). Artemether/lumefantrine should not be used in patients with cardiac arrhythmias, bradycardia, severe cardiac disease, or QT prolongation. Concomitant use of drugs that prolong the QT interval or are metabolized by CYP2D6 is contraindicated (*Med Lett Drugs Ther*. 2009;51:75).

11. Available in the United States in a 324-mg capsule; 2 capsules suffice for adult dosage. In Southeast Asia, relative resistance to quinine has increased and treatment should be continued for 7 days. For infections acquired elsewhere treatment can be given for 3 d. Quinine should be taken with or after meals to decrease gastrointestinal adverse effects. It is generally considered safe in pregnancy.

12. Not FDA approved for this indication.

13. Use of tetracyclines is contraindicated in pregnancy and in children <8 yd. Tetracycline should be taken 1 hour before or 2 hours after meals and/or dairy products.

14. Doxycycline should be taken with adequate water to avoid esophageal irritation. It can be taken with food to minimize gastrointestinal adverse effects.

15. Oral clindamycin should be taken with a full glass of water to minimize esophageal ulceration.

16. For use in pregnancy and in children <8 y.

17. Lell B, Kremsner PG. *Antimicrob Agents Chemother*. 2002;46:2315; Ramharter M, et al. *Clin Infect Dis*. 2005;40:1777.

18. At this dosage, adverse effects include nausea, vomiting, diarrhea, and dizziness. Disturbed sense of balance, ringing of the ears, toxic psychosis (and other psychiatric effects) and seizures can also occur. Mefloquine can be used for treatment of malaria in pregnant women. The FDA reclassified mefloquine to pregnancy category B based on a review of published data (Schlagenhauf P, et al. *Clin Infect Dis*. 2012;54:e124). It should be avoided for treatment of malaria in persons with active depression or with a history of psychosis or seizures and should be used with caution in persons with any psychiatric illness. Mefloquine should not be used in patients with conduction abnormalities; it can be given to patients taking β -blockers if they do not have an underlying arrhythmia. Mefloquine should not be given together with quinine or quinidine, and caution is required in using quinine or quinidine to treat patients with malaria who have taken mefloquine for prophylaxis. Mefloquine should not be taken on an empty stomach; it should be taken with at least 8 oz of water.

19. *P. falciparum* with resistance to mefloquine is a significant problem in the malarious areas of Thailand and in areas of Myanmar and Cambodia that border on Thailand. It has also been reported on the borders between Myanmar and China, Laos and Myanmar, and in Southern Vietnam. In the United States, a 250-mg tablet of mefloquine contains 228 mg mefloquine base. Outside the United States, each 275-mg tablet contains 250 mg base.

20. Primaquine phosphate can cause hemolytic anemia, especially in patients whose red cells are deficient in G6PD. This deficiency is most common in African, Asian, and Mediterranean peoples. Patients should be screened for G6PD deficiency before treatment. Limited evidence suggests G6PD-deficient patients may be safely treated with a single weekly dose of primaquine 0.75 mg/kg for 8 wk. Resistance is not known to occur at a dose of 0.5 mg/kg daily for 14 d: suspected resistant strains may be treated with this daily dose for 28 d. Relapse despite adherence to a full primaquine dose may be due to a poor metabolizer phenotype. Primaquine should not be used during pregnancy. It should be taken with food to minimize nausea and abdominal pain.

21. Combination therapy with dihydroartemisinin/piperaquine (Euartesim) plus primaquine has demonstrated safety, efficacy, and tolerability for treatment of *P. vivax* (Sutanto I, et al. *Antimicrob Agents Chemother*. 2013;57:1128).

22. *Medical Letter* consultants recommend this combination. Published data on safety or efficacy for cure of *P. vivax* is lacking (Baird JK, et al. *Antimicrob Agent Chemother*. 2011;55:1827).

23. Chloroquine should be taken with food to decrease gastrointestinal adverse effects. If chloroquine phosphate is not available, hydroxychloroquine sulfate is as effective; 400 mg of hydroxychloroquine sulfate is equivalent to 500 mg of chloroquine phosphate.

Continued

Malaria, Treatment (*Plasmodium falciparum*,¹ *P. vivax*,² *P. ovale*, *P. malariae*,³ and *P. knowlesi*⁴)—cont'd

Drug	Adult Dosage	Pediatric Dosage
Parenteral (Severe Infection)⁵		
All <i>Plasmodium</i> spp. (Chloroquine Sensitive and Resistant)		
Drug of choice ^{6,24} :	Quinidine gluconate ²⁵	10 mg/kg IV loading dose (max 600 mg) in normal saline over 1–2 h, followed by continuous infusion of 0.02 mg/kg/min until PO therapy can be started
<i>Or</i>	Quinine dihydrochloride ^{25*}	20 mg/kg IV loading dose in 5% dextrose over 4 h, followed by 10 mg/kg over 2–4 h q8h (max 1800 mg/d) until PO therapy can be started
<i>Or</i>	Artesunate ^{9,26*}	2.4 mg/kg/dose IV × 3 d at 0, 12, 24, 48 and 72 h
<i>Plus a second oral drug²⁶</i>		

24. Exchange transfusion is controversial but has been helpful for some patients with high-density (>10%) parasitemia, altered mental status, pulmonary edema, or renal complications (Van Genderen PJ, et al. *Transfusion*. 2009;Nov 20).

25. Continuous electrocardiographic, blood pressure, and glucose monitoring are recommended. Quinine IV is not available in the United States. Quinidine may have greater antimalarial activity than quinine. The loading dose should be decreased or omitted in patients who have received quinine or mefloquine. If more than 48 h of parenteral treatment are required, the quinine or quinidine dose should be reduced by 30–50%. Intrarectal quinine has been tried for the treatment of cerebral malaria in children (Achan J, et al. *Clin Infect Dis*. 2007;45:1446).

26. Oral artesunate is not available in the United States; the IV formulation is available through the CDC Malaria branch (M-F 9 am-5 pm ET, 770-488-7788 or 855-856-4713, or after hours, 770-488-7100) under an IND for patients with severe disease who do not have timely access, cannot tolerate, or fail to respond to IV quinidine (*Med Lett Drugs Ther*. 2008;50:37). To avoid development of resistance, adults treated with artesunate must also receive oral treatment doses of either atovaquone/proguanil, doxycycline, clindamycin or mefloquine; children should take either atovaquone/proguanil, clindamycin, or mefloquine (Nosten F, et al. *Lancet*. 2000;356:297; van Vugt M. *Clin Infect Dis*. 2002;35:1498; Smithuis F, et al. *Trans R Soc Trop Med Hyg*. 2004;98:182). If artesunate is given IV, oral medication should be started when the patient is able to tolerate it (SEQUAMAT group, *Lancet*. 2005;366:717; Duffy PE, Sibley CH, *Lancet*. 2005;366:1908). Reduced susceptibility to artesunate characterized by slow parasitic clearance has been reported in Cambodia (Rogers WO, et al. *Malaria J*. 2009;8:10; Dundorp AM, et al. *N Engl J Med*. 2009;361:455).

Malaria, Self-Presumptive Treatment¹

	Drug	Adult Dosage	Pediatric Dosage
Drug of Choice:	Atovaquone/proguanil ^{2,3}	4 adult tabs once/d or 2 adult tabs bid × 3 d ⁴	<5 kg: not indicated 5–8 kg: 2 peds tabs once/d × 3 d 9–10 kg: 3 peds tabs once/d × 3 d 11–20 kg: 1 adult tab once/d × 3 d 21–30 kg: 2 adult tabs once/d × 3 d 31–40 kg: 3 adult tabs once/d × 3 d >40 kg: 4 adult tabs once/d × 3 d ⁴
Or	Artemether/lumefantrine ^{2,5,6}	6 doses over 3 d (4 tabs/dose at 0, 8, 24, 36, 48, and 60 hours)	6 doses over 3 d at same intervals as adults 5–15 kg: 1 tab/dose 15–25 kg: 2 tabs/dose 25–35 kg: 3 tabs/dose >35 kg: 4 tabs/dose
Or	Quinine sulfate	650 mg PO q8h × 3 or 7 d ^{7,8}	30 mg/kg/d PO in 3 doses × 3 or 7 d ⁷
Plus	Doxycycline ^{2,9,10}	100 mg PO bid × 7 d	4 mg/kg/d PO in 2 doses × 7 d

1. A traveler can be given a course of medication for presumptive self-treatment of febrile illness. The drug given for self-treatment should be different from that used for prophylaxis. This approach should be used only in very rare circumstances when a traveler would not be able to get medical care promptly.

2. Not FDA approved for this indication.

3. Atovaquone/proguanil is available as a fixed-dose combination tablet: adult tablets (Malarone; atovaquone 250 mg/proguanil 100 mg) and pediatric tablets (Malarone pediatric; atovaquone 62.5 mg/proguanil 25 mg). To enhance absorption and reduce nausea and vomiting, it should be taken with food or a milky drink. Safety in pregnancy is unknown and use is generally not recommended. In a few small studies outcomes were normal in women treated with the combination in the 2nd and 3rd trimester (Pasternak B, et al. *Arch Intern Med*. 2011;171:259; AK Boggild et al. *Am J Trop Med Hyg*. 2007;76:208). The drug should not be given to patients with severe renal impairment (creatinine clearance <30 mL/min). There have been isolated case reports of resistance in *P. falciparum* in Africa, but *Medical Letter* consultants do not believe there is a high risk for acquisition of Malarone-resistant disease (Schwartz E, et al. *Clin Infect Dis*. 2003;37:450; Farnert A, et al. *BMJ*. 2003;326:628; Kuhn S, et al. *Am J Trop Med Hyg*. 2005;72:407; Happi CT, et al. *Malaria J*. 2006;5:82).

4. Although approved for once-daily dosing, *Medical Letter* consultants usually divide the dose in two to decrease nausea and vomiting.

5. Artemether is frequently used globally in combination regimens to treat malaria. It is available in oral, parenteral, and rectal formulations, but manufacturing standards are not consistent (Karunajeewa HA, et al. *JAMA*. 2007;297:2381; Ashley EA, White NJ. *Curr Opin Infect Dis*. 2005;18:531). Based on the few studies available, artemesin derivatives have been relatively safe during pregnancy (Adam I, et al. *Am Trop Med Parasitol*. 2009;103:205; Manyando C, et al. *Malaria J*. 2012;11:141), but some experts would not prescribe them in the 1st trimester (Clark RL. *Reprod Toxicol*. 2009;28:285).

6. Artemether/lumefantrine is available as a fixed-dose combination tablet (Coartem in the United States and in countries with endemic malaria; Riamet in Europe and countries without endemic malaria); each tablet contains artemether 20 mg and lumefantrine 120 mg. It is FDA approved for treatment of uncomplicated malaria and should not be used for severe infection or for prophylaxis. The tablets should be taken with fatty food (tablets may be crushed and mixed with 1–2 tsp water, then taken with milk). Artemether/lumefantrine should not be used in patients with cardiac arrhythmias, bradycardia, severe cardiac disease, or QT prolongation. Concomitant use of drugs that prolong the QT interval or are metabolized by CYP2D6 is contraindicated (*Med Lett Drugs Ther*. 2009;51:75).

7. For treatment of multiple-drug-resistant *P. falciparum* in Southeast Asia, especially Thailand, where mefloquine resistance is frequent, atovaquone/proguanil, quinine plus either doxycycline or clindamycin, or artemether/lumefantrine may be used. For infections acquired elsewhere treatment can be given for 3 d.

8. Available in the United States in a 324-mg capsule; 2 capsules suffice for adult dosage. In Southeast Asia, relative resistance to quinine has increased and treatment should be continued for 7 d. Quinine should be taken with or after meals to decrease gastrointestinal adverse effects. It is generally considered safe in pregnancy.

9. Use of tetracyclines is contraindicated in pregnancy and in children <8 y. Tetracycline should be taken 1 hour before or 2 hours after meals and/or dairy products.

10. Doxycycline should be taken with adequate water to avoid esophageal irritation. It can be taken with food to minimize gastrointestinal adverse effects.

Malaria, Prevention¹

	Drug	Adult Dosage	Pediatric Dosage
All <i>Plasmodium</i> spp. in Chloroquine-Resistant Areas²⁻⁵			
Drug of choice:	Atovaquone/proguanil ^{6,7}	1 adult tab/d ⁸	5–8 kg: ½ peds tab/d ^{7,8} 9–10 kg: ¾ peds tab/d ^{7,8} 11–20 kg: 1 peds tab/d ^{7,8} 21–30 kg: 2 peds tabs/d ^{7,8} 31–40 kg: 3 peds tabs/d ^{7,8} >40 kg: 1 adult tab/d ^{7,8}
Or	Doxycycline ^{6,9,10}	100 mg PO daily ¹¹	2 mg/kg/d PO, up to 100 mg/d ¹¹
Or	Mefloquine ^{6,12,13}	250 mg PO once/wk ¹⁴	≤ 9 kg: 5 mg/kg salt once/wk ¹⁴ 9–19 kg: ¼ tab once/wk ¹⁴ >19–30 kg: ½ tab once/wk ¹⁴ >31–45 kg: ¾ tab once/wk ¹⁴ >45 kg: 1 tab once/wk ¹⁴
Alternative ¹⁵ :	Primaquine ^{16,17} phosphate	30 mg base PO daily	0.5 mg/kg base PO daily
All <i>Plasmodium</i> spp. in Chloroquine-Sensitive Areas²⁻⁵			
Drug of choice ^{6,18} :	Chloroquine phosphate ^{6,19,20}	500 mg (300 mg base) PO once/wk ²¹	5 mg/kg base PO once/wk, up to adult dose of 300 mg base ²¹

1. No drug guarantees protection against malaria. Travelers should be advised to seek medical attention if fever develops after they return. Insect repellents, insecticide-impregnated bed nets and proper clothing are important adjuncts for malaria prophylaxis (*Treat Guidel Med Lett*. 2009;7:83). Malaria in pregnancy is particularly serious for both mother and fetus; prophylaxis is indicated if exposure cannot be avoided.

2. Chloroquine-resistant *P. falciparum* occurs in all malarious areas except Central America (including Panama north and west of the Canal Zone), Mexico, Haiti, the Dominican Republic, Paraguay, northern Argentina, North and South Korea, Georgia, Armenia, most of rural China and some countries in the Middle East (chloroquine resistance has been reported in Yemen, Saudi Arabia, and Iran).

3. Chloroquine-resistant *P. vivax* is a significant problem in Papua-New Guinea and Indonesia. There are also reports of resistance from Myanmar, Vietnam, Korea, India, the Solomon Islands, Vanuatu, Indonesia, Guyana, Brazil, Colombia, and Peru (Baird JK, *Clin Microbiol Rev*. 2009;22:508).

4. Chloroquine-resistant *P. malariae* has been reported from Sumatra (Maguire JD, et al. *Lancet*. 2002;360:58).

5. Human infection with the simian species, *P. knowlesi*, has been reported in Malaysia, where it was initially misdiagnosed as *P. malariae*. Additional cases have been reported from Thailand, Myanmar, Singapore, the Thai-Burma border, and the Philippines (Cox-Singh J, et al. *Clin Infect Dis*. 2008;46:165; *MMWR*. 2009;58:229).

6. Vivax malaria is a potentially more dangerous infection that previously thought (Baird JK, et al. *Microbiol Rev*. 2013;26:36). Some *Medical Letter* consultants recommend primaquine as first choice for primary prophylaxis in areas where *P. vivax* is endemic. Atovaquone/proguanil, doxycycline, mefloquine, and chloroquine have no activity against latent liver stages of *P. vivax* or *P. ovale*. In one randomized study travelers taking mefloquine (52%) or doxycycline (53%) developed acute *P. vivax* malaria more than 1 mo after travel, while travelers taking daily primaquine had a 6% attack rate (Schwartz I, Regev-Yochay G. *Clin Infect Dis*. 1999;29:1502). Other *Medical Letter* consultants prescribe primaquine phosphate 30 mg base/d (0.6 mg base/kg/d for children) in addition to another drug taken during travel for 14 d after departure from areas where *P. vivax* or *P. ovale* are endemic (presumptive anti-relapse therapy). Since this is not always effective for prevention (Schwartz E, et al. *N Engl J Med*. 2003;349:1510), still others prefer to rely on surveillance to detect cases when they occur, particularly when exposure was limited or doubtful. See also footnote 17.

7. Atovaquone/proguanil is available as a fixed-dose combination tablet: adult tablets (Malarone; atovaquone 250 mg/proguanil 100 mg) and pediatric tablets (Malarone pediatric; atovaquone 62.5 mg/proguanil 25 mg). To enhance absorption and reduce nausea and vomiting, it should be taken with food or a milky drink. Safety in pregnancy is unknown and use is generally not recommended. In a few small studies outcomes were normal in women treated with the combination in the 2nd and 3rd trimester (Paternak B, et al. *Arch Intern Med*. 2011;171:259; Boggild AK, et al. *Am J Trop Med Hyg*. 2007;76:208). The drug should not be given to patients with severe renal impairment (creatinine clearance <30 mL/min). There have been isolated case reports of resistance in *P. falciparum* in Africa, but *Medical Letter* consultants do not believe there is a high risk for acquisition of Malarone-resistant disease (Schwartz E, et al. *Clin Infect Dis*. 2003;37:450; Aarnert A, et al. *BMJ*. 2003;326:628; Kuhn S, et al. *Am J Trop Med Hyg*. 2005;72:407; Happi CT, et al. *Malaria J*. 2006;5:82).

8. Beginning 1–2 d before travel and continuing for the duration of stay and for 1 wk after leaving malarious zone. In one study of malaria prophylaxis, atovaquone/proguanil was better tolerated than mefloquine in nonimmune travelers (Overbosch D, et al. *Clin Infect Dis*. 2001;33:1015). The protective efficacy of Malarone against *P. vivax* is variable ranging from 84% in Indonesian New Guinea (Ling J, et al. *Clin Infect Dis*. 2002; 35:825) to 100% in Colombia (Soto J, et al. *Am J Trop Med Hyg*. 2006;75:430). Some *Medical Letter* consultants prefer alternate drugs if traveling to areas where *P. vivax* predominates.

9. Use of tetracyclines is contraindicated in pregnancy and in children <8 y. Tetracycline should be taken 1 h before or 2 h after meals and/or dairy products.

10. Doxycycline should be taken with adequate water to avoid esophageal irritation. It can be taken with food to minimize gastrointestinal adverse effects.

11. Beginning 1–2 d before travel and continuing for the duration of stay and for 4 wk after leaving malarious zone. Doxycycline can cause gastrointestinal disturbances, vaginal moniliasis, and photosensitivity reactions.

12. *P. falciparum* with resistance to mefloquine is a significant problem in the malarious areas of Thailand and in areas of Myanmar and Cambodia that border on Thailand. It has also been reported on the borders between Myanmar and China, Laos and Myanmar, and in Southern Vietnam. In the United States, a 250-mg tablet of mefloquine contains 228 mg mefloquine base. Outside the United States, each 275-mg tablet contains 250 mg base.

13. Mefloquine can be used during pregnancy. The FDA reclassified mefloquine to pregnancy category B based on a review of published data (Schlagenhauf P, et al. *Clin Infect Dis*. 2012;54:e124). It is not recommended for use in travelers with active depression or with a history of psychosis or seizures and should be used with caution in persons with psychiatric illness. Mefloquine should not be used in patients with conduction abnormalities; it can be given to patients taking β-blockers if they do not have an underlying arrhythmia.

14. Beginning 1–2 wk before travel and continuing weekly for the duration of stay and for 4 wk after leaving malarious zone. Most adverse events occur within 3 doses. Some *Medical Letter* consultants favor starting mefloquine 3 weeks prior to travel and monitoring the patient for adverse events; this allows time to change to an alternative regimen if mefloquine is not tolerated. Mefloquine should not be taken on an empty stomach; it should be taken with at least 8 oz of water. For pediatric doses < ½ tablet, it is advisable to have a pharmacist crush the tablet, estimate doses by weighing, and package them in gelatin capsules. There is no data for use in children <5 kg, but based on dosages in other weight groups, a dose of 5 mg/kg can be used.

15. The combination of weekly chloroquine (300 mg base) and daily proguanil (200 mg) is recommended by the World Health Organization for use in selected areas; this combination is no longer recommended by the CDC. Proguanil (Paludrine; AstraZeneca, United Kingdom) is not available alone in the United States but is widely available in Canada and Europe. Prophylaxis is recommended during exposure and for 4 weeks afterwards. Proguanil has been used in pregnancy without evidence of toxicity (Phillips-Howard PA, Wood D. *Drug Saf*. 1996;14:131).

16. Not FDA approved for this indication.

17. Primaquine used as primary prophylaxis has proven good safety, tolerability, and efficacy when used in nonpregnant, G6PD-normal travelers (Hill DR, et al. *Am J Trop Med Hyg*. 2006;75:402–15). Beginning the day of travel and for 5 days following travel, this regimen prevents primary attacks of *P. falciparum* and *P. vivax*, and of secondary attacks (relapses) by *P. vivax* in the months following travel. Primaquine can cause hemolytic anemia, especially in patients whose red cells are deficient in G6PD. This deficiency is most common in African, Asian, and Mediterranean peoples. Patients should be screened for G6PD deficiency before treatment. Limited evidence suggests G6PD-deficient patients may be safely treated with a single weekly dose of primaquine 0.75 mg/kg for 8 weeks. Resistance is not known to occur at a dose of 0.5 mg/kg daily for 14 days: suspected resistant strains may be treated with this daily dose for 28 days. Relapse despite adherence to a full primaquine dose may be due to a poor metabolizer phenotype. Primaquine should not be used during pregnancy. It should be taken with food to minimize nausea and abdominal pain.

18. Alternatives for patients who are unable to take chloroquine include atovaquone/proguanil, mefloquine, doxycycline, or primaquine dosed as for chloroquine-resistant areas.

19. Chloroquine should be taken with food to decrease gastrointestinal adverse effects. If chloroquine phosphate is not available, hydroxychloroquine sulfate is as effective; 400 mg of hydroxychloroquine sulfate is equivalent to 500 mg of chloroquine phosphate.

20. Has been used extensively and safely for prophylaxis in pregnancy.

21. Beginning 1–2 wk before travel and continuing weekly for the duration of stay and for 4 wk after leaving malarious zone.

Microsporidiosis

	Drug	Adult Dosage	Pediatric Dosage
Ocular (<i>Encephalitozoon hellem</i>, <i>E. cuniculi</i>, <i>Vittaforma</i> [<i>Nosema</i>] <i>corneae</i>)			
Drug of choice:	Fumagillin ^{1*}		
	Plus		
	albendazole ^{2,3}	400 mg PO bid	15 mg/kg/d in 2 doses (max 400 mg/dose)
Intestinal (<i>E. bienersi</i>, <i>E. [Septata] intestinalis</i>)			
<i>E. bienersi</i>			
Drug of choice:	Fumagillin ^{4*}	20 mg PO tid × 14 d	
<i>E. intestinalis</i>			
Drug of choice:	Albendazole ^{2,3}	400 mg PO bid × 21 d	15 mg/kg/d in 2 doses (max 400 mg/dose)
Disseminated (<i>E. hellem</i>, <i>E. cuniculi</i>, <i>E. intestinalis</i>, <i>Pleistophora</i> sp., <i>Trachipleistophora</i> spp. and <i>Anncaliia</i> [<i>Brachiola</i>] <i>vesicularum</i>)			
Drug of choice ⁵ :	Albendazole ^{2,3}	400 mg PO bid	15 mg/kg/d in 2 doses (max 400 mg/dose)

*Availability problems. See Table 241.2.

1. Chan CM, et al. *Ophthalmology*. 2003;110:1420. Ocular lesions due to *E. hellem* in HIV-infected patients have responded to fumagillin eyedrops prepared from Fumidil-B (bicyclohexyl ammonium fumagillin) used to control a microsporidial disease of honey bees (Garvey MJ, et al. *Ann Pharmacother*. 1995;29:872), available from Leiter's Park Avenue Pharmacy, San Jose, CA (800-292-6773; www.leiterrx.com), a compounding pharmacy that specializes in ophthalmic drugs. For lesions due to *V. corneae*, topical therapy is generally not effective and keratoplasty may be required (Davis RM, et al. *Ophthalmology*. 1990;97:953).

2. Not FDA approved for this indication.

3. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

4. Oral fumagillin (Flisint; Sanofi-Aventis, France) has been effective in treating *E. bienersi* in patients with HIV or solid organ transplants (Molina J-M, et al. *N Engl J Med*. 2002;346:1963; Lanternier F, et al. *Transpl Infect Dis*. 2009;11:83) but has been associated with thrombocytopenia and neutropenia. Potent antiretroviral therapy may lead to microbiologic and clinical response in HIV-infected patients with microsporidial diarrhea. Octreotide (Sandostatin) has provided symptomatic relief in some patients with large-volume diarrhea.

5. Molina J-M, et al. *J Infect Dis*. 1995;171:245. There is no established treatment for *Pleistophora*. For disseminated disease due to *Trachipleistophora* or *Anncaliia*, itraconazole 400 mg PO once/d plus albendazole may also be tried (Coyle Cm, et al. *N Engl J Med*. 2004;351:42).

Or	Dapsone ³	50 mg PO daily or 200 mg PO each wk	
Plus	pyrimethamine ⁸	50 mg PO daily or 75 mg PO each wk	
Or	Atovaquone ^{3,6}	1500 mg/d PO in 1 or 2 doses	1–3 mo: 30 mg/kg/d PO 4–24 mo: 45 mg/kg/d PO >24 mo: 30 mg/kg/d PO
Or	Pentamidine	300 mg aerosol inhaled monthly via <i>Respirgard II</i> nebulizer	≥5 y: 300 mg inhaled monthly via <i>Respirgard II</i> nebulizer

SMX, Sulfamethoxazole; TMP, trimethoprim.

1. Pneumocystis has been reclassified as a fungus (Gilroy SA, Bennett NJ. *Semin Respir Crit Care Med*. 2011;32:775).2. In severe disease with room air PO₂ ≤70 mm Hg or Aa gradient ≥35 mm Hg, prednisone or its IV equivalent should also be used. For adults: days 1–5: 40 mg PO bid; days 6–10: 40 mg PO daily; days 11–21: 20 mg PO daily. For children: days 1–5: 2 mg/kg/d PO in 2 doses; days 6–10: 1 mg/kg/d PO in 2 doses; days 11–21: 0.5 mg/kg/d PO daily (Kaplan JE, et al. *Morbidity Mortality Wkly Rep*. 2009;58[RR04]:1; *Morbidity Mortality Wkly Rep*. 2009;58[RR11]:1).

3. Not FDA approved for this indication.

4. Primaquine phosphate can cause hemolytic anemia, especially in patients deficient in G6PD. This deficiency is most common in African, Asian, and Mediterranean peoples. Patients should be screened for G6PD deficiency before treatment. Primaquine should not be used during pregnancy. It should be taken with food to minimize nausea and abdominal pain.

5. Oral clindamycin should be taken with a full glass of water to minimize esophageal ulceration.

6. Atovaquone is available in an oral suspension that should be taken with a meal to increase absorption.

7. Primary/secondary prophylaxis in patients with HIV can be discontinued after CD4 count increases to >200 × 10⁶/L for >3 mo.

8. Plus leucovorin 25 mg with each dose of pyrimethamine. Pyrimethamine should be taken with food to minimize gastrointestinal adverse effects.

River BlindnessSee [Filariasis](#)**Roundworm**See [Ascariasis](#)***Sarcocystis* spp. (Intestinal and Muscular)**

Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	Sarcocystis in humans is acquired by ingesting sporocysts in infected meat. Infection is characterized by nausea, abdominal pain and diarrhea. Most muscle infections are mild or subclinical, although severe and prolonged muscle pain has been reported. ¹ Albendazole was reported to be efficacious. ²	

1. Fayer R. *Clin Microbiol Rev.* 2004;17:894; *MMWR Morb Mortal Wkly Rep.* 2012;61:37.2. Amess MK, et al. *Am J Trop Med Hyg.* 1999;61:548.**Scabies (*Sarcoptes scabiei*)¹**

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	5% Permethrin	Topically, 2 × at least 7 d apart	Topically, 2 × at least 7 d apart
Alternative:	Ivermectin ^{2,3}	200 µg/kg PO 2 × at least 7 d apart ⁴	200 µg/kg PO, 2 × at least 7 d apart ⁴
	10% crotamiton	Topically overnight on days 1, 2, 3, 8	Topically overnight on days 1, 2, 3, 8

1. Meinking TL, et al. Infestations. In: Schachner LA, Hansen RC, eds. *Pediatric Dermatology*. 4th ed. St Louis: Mosby; 2011:1535; Hay RJ, et al. *Clin Microbiol Infect.* 2012;18:313.

2. Not FDA approved for this indication.

3. Gonzalez P, et al. *Curr Pharm Biotechnol.* 2012;13:1103. Safety of ivermectin in young children (<15 kg) and pregnant women remains to be established; animal studies have shown adverse effects on the fetus (el-Ashmawy IM, et al. *Res Vet Sci.* 2011;90:116). Taking ivermectin with a meal increases its bioavailability (Guzzo CA, et al. *J Clin Pharmacol.* 2002;42:1122).4. Currie BJ, McCarthy JS. *N Engl J Med.* 2010;362:717. A second ivermectin dose taken 2 weeks later increased the cure rate to 95%, which is equivalent to that of 5% permethrin (Usha V, et al. *J Am Acad Dermatol.* 2000;42:236). Ivermectin, either alone or in combination with a topical scabicide, is the drug of choice for crusted scabies in immunocompromised patients (del Giudice P. *Curr Opin Infect Dis.* 2004;15:123).**Schistosomiasis (Bilharziasis)¹**

	Drug	Adult Dosage	Pediatric Dosage
<i>S. haematobium</i>			
Drug of choice:	Praziquantel ^{2,3}	40 mg/kg/d PO in 1 or 2 doses × 1 d	40 mg/kg/d PO in 2 doses × 1 d
<i>S. intercalatum</i>⁴			
Drug of choice:	Praziquantel ^{2,3}	40 mg/kg/d PO in 1 or 2 doses × 1 d	40 mg/kg/d PO in 2 doses × 1 d
<i>S. japonicum</i>			
Drug of choice:	Praziquantel ^{2,3}	60 mg/kg/d PO in 2 or 3 doses × 1 d	60 mg/kg/d PO in 3 doses × 1 d
<i>S. mansoni</i>			
Drug of choice:	Praziquantel ^{2,3}	40 mg/kg/d PO in 1 or 2 doses × 1 d	40 mg/kg/d PO in 2 doses × 1 d
Alternative:	Oxamniquine ^{5*}	15 mg/kg PO once ⁶	20 mg/kg/d PO in 2 doses × 1 d ⁶
<i>S. mekongi</i>			
Drug of choice:	Praziquantel ^{2,3}	60 mg/kg/d PO in 2 or 3 doses × 1 d	60 mg/kg/d PO in 3 doses × 1 d

*Availability problems. See [Table 241.2](#).1. Praziquantel is the choice worldwide for treatment and prevention of schistosomiasis (Liu R, et al. *Parasit Vectors.* 2011;4:201). Artemisinin treatment early after exposure may decrease the risk of acute disease (Ross AG, et al. *Lancet Infect Dis.* 2007;7:218; Liu R, et al. *Parasitol Res.* 2012;110:2071). It was less effective than praziquantel in an open-label trial of 212 children in Kenya (Obonyo CO, et al. *Lancet Infect Dis.* 2010;10:603).

2. Praziquantel should be taken with liquids during a meal.

3. Retreatment in 2–6 weeks increases cure (Doenhoff MJ, et al. *Curr Opin Infect Dis.* 2008;21:659; Gray DJ, et al. *BMJ.* 2011;342:d2651).4. Geographically restricted to Central Western Africa and the island of São Tomé. Usually a disease of the lower GI tract; there are also case reports of complications including central nervous system, liver, and cardiopulmonary involvement (Murinello A, et al. *J Port Gastroenterol.* 2006;13:97).5. Oxamniquine, which is not available in the United States, is generally not as effective as praziquantel. It has been useful, however, in some areas in which praziquantel is less effective (Ferrari ML, et al. *Bull World Health Organ.* 2003;81:190; Harder A, *Parasitol Res.* 2002;88:395). Oxamniquine is contraindicated in pregnancy. It should be taken after food.6. In East Africa, the dose should be increased to 30 mg/kg PO, and in Egypt and South Africa to 30 mg/kg/d PO × 2 d. Some experts recommend 40–60 mg/kg PO over 2–3 d in all of Africa (Shekhar KC. *Drugs.* 1991;42:379).**Sleeping Sickness**See [Trypanosomiasis](#)

Strongyloidiasis (*Strongyloides stercoralis*)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice ¹ :	Ivermectin ²	200 µg/kg/d PO × 2 d	200 µg/kg/d PO × 2 d
Alternative:	Albendazole ^{3,4}	400 mg PO bid × 7 d	400 mg PO bid × 7 d

1. In immunocompromised patients or disseminated disease (strongyloides hyperinfection syndrome) additional doses or use of other drugs may be necessary. Veterinary subcutaneous and enema formulations of ivermectin have been used in severely ill patients with hyperinfection who were unable to take or reliably absorb oral medications (Marty fm, et al. *Clin Infect Dis*. 2005;41:e5; Lichtenberger p, et al. *Transpl Infect Dis*. 2009;11:137).

2. Gonzalez p, et al. *Curr Pharm Biotechnol*. 2012;13:1103. Safety of ivermectin in young children (<15 kg) and pregnant women remains to be established; animal studies have shown adverse effects on the fetus (el-Ashmawy im, et al. *Res Vet Sci*. 2011;90:116). Taking ivermectin with a meal increases its bioavailability (Guzzo ca, et al. *J Clin Pharmacol*. 2002; 42:1122).

3. Not FDA approved for this indication.

4. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

Tapeworm Infection

	Drug	Adult Dosage	Pediatric Dosage
Adult (Intestinal Stage)			
Diphyllobothrium latum (Fish), Taenia saginata (Beef), Taenia solium (Pork), Dipylidium caninum (Dog)			
Drug of choice:	Praziquantel ^{1,2}	5–10 mg/kg PO once	5–10 mg/kg PO once
Alternative:	Niclosamide ^{3*}	2 g PO once	50 mg/kg PO once
Hymenolepis Nana (Dwarf Tapeworm)			
Drug of choice:	Praziquantel ^{1,2}	25 mg/kg PO once	25 mg/kg PO once
Alternative: ⁴	Niclosamide ^{3*}	2 g PO daily × 7 d	11–34 kg: 1 g PO on day 1 then 500 mg/d PO × 6 days > 34 kg: 1.5 g PO on day 1 then 1 g/d PO × 6 days
Larval (Tissue Stage)			
Echinococcus granulosus (Cystic Echinococcosis)			
Treatment of choice:		See footnote 5	
Drug of choice:	Albendazole ⁶	15 mg/kg/d (max 800 mg) PO in 2 doses × 1–6 mo	15 mg/kg/d (max 800 mg) PO in 2 doses × 1–6 mo
Echinococcus multilocularis (Alveolar Echinococcosis)			
Treatment of choice:		See footnote 7	
Drug of choice:	Albendazole ⁶	15 mg/kg/d (max 800 mg) PO in 2 doses × >2 y	
Taenia solium (Cysticercosis)			
Treatment of choice:		See footnote 8	
Alternative:	Albendazole ⁶	15 mg/kg/d (max 800 mg) PO in 2 doses × 8–30 d; can be repeated as necessary	15 mg/kg/d (max 800 mg) PO in 2 doses × 8–30 d; can be repeated as necessary
Or	Praziquantel ^{1,2}	50 mg/kg/d PO × 15 d	50 mg/kg/d PO × 15 d

*Availability problems. See Table 241.2.

1. Not FDA approved for this indication.

2. Praziquantel should be taken with liquids during a meal.

3. Niclosamide must be thoroughly chewed or crushed and swallowed with a small amount of water.

4. Nitazoxanide may be an alternative (Ortiz JJ, et al. *Trans R Soc Trop Med Hyg*. 2002;96:193; Chero JC, et al. *Trans R Soc Trop Med Hyg* 2007;101:203; Diaz E, et al. *Am J Trop Med Hyg*. 2003;68:384).

5. Treatment of uncomplicated hepatic or abdominal cysts is stage-dependent and ranges from surgical resection to watch and wait (Brunetti E, et al. *Acta Trop*. 2010;114:1). Patients may benefit from surgical resection (for larger cysts) or percutaneous drainage of cysts. Percutaneous aspiration-injection-reaspiration with ultrasound guidance plus albendazole therapy (1 wk before and for 30 d after) has been effective for management of hepatic hydatid cyst disease (Golemanov B, et al. *Am J Trop Med Hyg*. 2011;84:48; Gupta N, et al. *J Gastrointest Surg*. 2011;15:1829). Praziquantel may also be useful preoperatively or in case of spillage of cyst contents during surgery.

6. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

7. Surgical excision is the only reliable means of cure (but is rarely possible) and should be followed by prolonged albendazole therapy (Kern P. *Curr Opin Infect Dis*. 2010;23:505). Reports have suggested that in nonresectable cases, long-term (months to years) use of albendazole (400 mg bid) can stabilize and rarely cure infection (Moro P, Schantz PM. *Int J Infect Dis*. 2009;13:125; Chappius F. *Rev Med Suisse*. 2012;8:989).

8. Advances in neuroimaging using CT and MRI have facilitated the ability to make an accurate diagnosis (Del Brutto OH. *ScientificWorld J*. 2012;2012:159821; Nash TE, Garcia HH. *Nat Rev Neurol*. 2011;7:584). Initial therapy for patients with inflamed parenchymal cysticercosis should focus on symptomatic treatment with antiepileptic medication (Sinha S, Sharma BS. *J Clin Neurosci*. 2009;16:867). Patients with live parenchymal cysts who have seizures should be treated with albendazole together with steroids and an antiepileptic medication (Garcia HH, et al. *Curr Opin Infect Dis*. 2011;24:423). Patients with subarachnoid cysts or giant cysts in the fissures should be treated for at least 30 days (Proaño JV, et al. *N Engl J Med*. 2001;345:879). Surgical intervention (especially neuroendoscopic removal) or cerebrospinal fluid diversion followed by albendazole and steroids is indicated for obstructive hydrocephalus. Arachnoiditis, vasculitis or cerebral edema is treated with albendazole or praziquantel plus prednisone (60 mg/d) or dexamethasone (4–6 mg/d). Any cysticidal drug may cause irreparable damage when used to treat ocular or spinal cysts, even when corticosteroids are used. An ophthalmic exam should always precede treatment to rule out intraocular cysts.

Toxocariasis

See **Visceral Larva Migrans**

Toxoplasmosis (*Toxoplasma gondii*)

	Drug	Adult Dosage	Pediatric Dosage
CNS Disease¹			
Drug of choice:	Pyrimethamine ²	200 mg PO × 1 then 50–75 mg/d PO × 3–6 wk	2 mg/kg/d PO × 2 d, then 1 mg/kg/d (max 25 mg/d) × 3–6 wk
Plus	Sulfadiazine ³	1–1.5 g PO qid × 3–6 wk	100–200 mg/kg/d divided q6h PO × 3–6 wk
Or	Clindamycin ^{4,5,6}	1.8–2.4 g/d IV or PO in 3 or 4 doses	5–7.5 mg/kg/d IV or PO in 3 or 4 doses (max 600 mg/dose)
Or	Atovaquone ^{4,5,7}	1500 mg PO bid	1500 mg PO bid
Alternative:	TMP-SMX ⁴	TMP 15–20 mg/kg/d, SMX 75–100 mg/kg/d PO or IV in 3 or 4 doses	TMP 15–20 mg/kg/d, SMX 75–100 mg/kg/d PO or IV in 3 or 4 doses
Primary Infection in Pregnancy			
Treatment of choice: See footnote 8			

SMX, Sulfamethoxazole; TMP, trimethoprim.

1. Treatment is followed by chronic suppression with lower dosage regimens of the same drugs. In the United States, for primary prophylaxis of HIV patients with CD4 <100 × 10⁶ cells/L (outside the United States, CD4 <200 × 10⁶ cells/L), either TMP-SMX, pyrimethamine with dapsone, or atovaquone with or without pyrimethamine can be used (TMP-SMX is generally preferred due to once-daily dosing). Primary or secondary prophylaxis may be discontinued when the CD4 count increases to >200 × 10⁶ cells/L for >3 mo (MMWR Morb Mortal Wkly Rep. 2009;58[RR4]:1). In ocular toxoplasmosis with macular involvement, corticosteroids are recommended in addition to antiparasitic therapy (Montoya JG, Liesenfeld O. *Lancet*. 2004;363:1965).

2. Plus leucovorin 10–25 mg with each dose of pyrimethamine. Pyrimethamine should be taken with food to minimize gastrointestinal adverse effects.

3. Sulfadiazine should be taken on an empty stomach with adequate water.

4. Not FDA approved for this indication.

5. Clindamycin has been used in combination with pyrimethamine to treat CNS toxoplasmosis in HIV-infected patients who developed sulfonamide sensitivity while on sulfadiazine.

Atovaquone has also been used to treat sulfonamide-intolerant patients (Chirgwin K, et al. *Clin Infect Dis*. 2002;34:1243).

6. Oral clindamycin should be taken with a full glass of water to minimize esophageal ulceration.

7. Atovaquone is available in an oral suspension that should be taken with a meal to increase absorption.

8. Women who develop toxoplasmosis during the first trimester of pregnancy should be treated with spiramycin (3–4 g/d). After the first trimester, if there is no documented transmission to the fetus, spiramycin can be continued until term. Spiramycin is not currently available in the United States but can be obtained at no cost from Aventis through an IND from the FDA (301-796-1600) following confirmation of the diagnosis by a recognized laboratory (e.g., Palo Alto Medical Foundation, Toxoplasmosis Laboratory 650-853-4828). If transmission has occurred in utero, therapy with pyrimethamine and sulfadiazine should be started. Pyrimethamine is a potential teratogen and should be used only after the first trimester (Montoya JG, Remington JS. *Clin Infect Dis*. 2008;47:554). Congenitally infected newborns should be treated with pyrimethamine every 2 or 3 days and a sulfonamide daily for about 1 y (Remington JS. *Infectious Disease of the Fetus and Newborn Infant*, 7th ed. Philadelphia: Saunders; 2011:918).

Trichinellosis (*Trichinella spiralis* and Other *Trichinella* spp.)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice ¹ :	Steroids for severe symptoms	prednisone 30–60 mg PO daily × 10–15 d	
Plus	Albendazole ^{2,3}	400 mg PO bid × 8–14 d	400 mg PO bid × 8–14 d
Alternative:	Mebendazole ²	200–400 mg PO tid × 3 d, then 400–500 mg tid × 10 d	200–400 mg PO tid × 3 d, then 400–500 mg tid × 10 d

1. Gottstein B, et al. *Clin Microbiol Rev*. 2009;22:127.

2. Not FDA approved for this indication.

3. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

Trichomoniasis (*Trichomonas vaginalis*)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice ¹ :	Tinidazole ²	2 g PO once	50 mg/kg once (max 2 g)
Or	Metronidazole ³	2 g PO once	15 mg/kg/d PO in 3 doses × 7 d

1. Sexual partners should be treated simultaneously with same dosage. If treatment failure occurs with metronidazole 2 g single dose and reinfection is excluded, treat with metronidazole 500 mg PO bid × 7 d. For patients taking 7 d of metronidazole, metronidazole or tinidazole 2 g PO daily × 5 d should be considered. Consultation and susceptibility testing is available from the CDC 404-718-4141 (MMWR Morb Mortal Wkly Rep. 2010;59[RR-12]:1).

2. A nitroimidazole similar to metronidazole, tinidazole appears to be at least as effective as metronidazole and better tolerated. It should be taken with food to minimize adverse GI effects. For children and patients unable to take tablets, a pharmacist can crush the tablets and mix them with cherry syrup (Humco, and others). The syrup suspension is good for 7 days at room temperature and must be shaken before use (Fung HB, Doan TL. *Clin Ther*. 2005;27:1859). Ornidazole, a similar drug, is also used outside the United States.

3. Metronidazole has been associated with higher rates of parasitologic and clinical failure compared to tinidazole (Bachmann LH, et al. *Clin Infect Dis*. 2011; 53[Suppl 3]:S160).

Trichostrongylus Infection

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	Pyrantel pamoate ^{1,2}	11 mg/kg base PO once (max 1 g)	11 mg/kg base PO once (max 1 g)
Alternative:	Mebendazole ¹	100 mg PO bid × 3 d	100 mg PO bid × 3 d
Or	Albendazole ^{1,3}	400 mg PO once	400 mg PO once

1. Not FDA approved for this indication.

2. Available without a prescription. Pyrantel pamoate suspension can be mixed with milk or fruit juice.

3. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

Trichuriasis (*Trichuris trichiura*, Whipworm)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	Albendazole ^{1,2}	400 mg PO × 3 d	400 mg PO × 3 d
Alternative:	Mebendazole	100 mg PO bid × 3 d	100 mg PO bid × 3 d
Or	Ivermectin ^{1,3,4}	200 mcg/kg/d PO × 3 d	200 mcg/kg/d PO × 3 d

1. Not FDA approved for this indication.

2. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

3. Gonzalez P, et al. *Curr Pharm Biotechnol*. 2012;13:1103. Safety of ivermectin in young children (<15 kg) and pregnant women remains to be established; animal studies have shown adverse effects on the fetus (el-Ashmawy IM, et al. *Res Vet Sci*. 2011;90:116). Taking ivermectin with a meal increases its bioavailability (Guzzo CA, et al. *J Clin Pharmacol*. 2002;42:1122).

4. Ivermectin alone is less effective than albendazole or mebendazole. Addition of ivermectin to albendazole or mebendazole improved cure rates in one study (Knopp S, et al. *Clin Infect Dis*. 2010;51:1420).

Trypanosomiasis

	Drug	Adult Dosage	Pediatric Dosage
<i>T. cruzi</i> (American Trypanosomiasis, Chagas' Disease)¹			
Drug of choice:	Benznidazole ^{2*}	5–7 mg/kg/d PO in 2 doses × 60 d	<12 y: 10 mg/kg/d PO in 2 doses × 60 d >12 y: 5–7 mg/kg/d PO in 2 doses × 60 d
Or	Nifurtimox [*]	8–10 mg/kg/d PO in 3–4 doses × 90 d	1–10 y: 15–20 mg/kg/d PO in 4 doses × 90 d 11–16 y: 12.5–15 mg/kg/d PO in 4 doses × 90 d
<i>T. brucei gambiense</i> (West African Trypanosomiasis, Sleeping Sickness)³			
Hemolymphatic Stage			
Drug of choice ⁴ :	Pentamidine ⁵	4 mg/kg/d IM or IV × 7 d	4 mg/kg/d IM or IV × 7 d
Alternative:	Suramin [*]	100 mg (test dose) IV, then 1 g IV on days 1,3,5,14, 21	2 mg/kg (test dose) IV, then 20 mg/kg IV on days 1,3,5,14, 21
Late Disease With Central Nervous System Involvement			
Drug of choice ⁶ :	Eflornithine ^{7*}	400 mg/kg/d IV in 4 doses × 14 d	400 mg/kg/d IV in 4 doses × 14 d
Or	Eflornithine ^{7*}	400 mg/kg IV in 2 doses × 7 d	
Plus	nifurtimox	15 mg/kg/d PO in 3 doses × 10 d	
Alternative:	Melarsoprol ⁸	2.2 mg/kg/d IV × 10 d	2.2 mg/kg/d IV × 10 d
<i>T. b. rhodesiense</i> (East African Trypanosomiasis, Sleeping Sickness)³			
Hemolymphatic Stage			
Drug of choice:	Suramin [*]	100 mg (test dose) IV, then 1 g IV on days 1,3,5,14, 21	2 mg/kg (test dose) IV, then 20 mg/kg IV on days 1,3,5,14, 21
Late Disease With CNS Involvement			
Drug of choice:	Melarsoprol ⁸	2.2 mg/kg/d IV × 10 d	2.2 mg/kg/d IV × 10 d

*Availability problems. See Table 241.2.

1. Treatment of chronic or indeterminate Chagas' disease with benznidazole has been associated with negative seroconversion in children and reduced progression of cardiac disease in adults (Viotti R, et al. *Ann Intern Med*. 2006;144:724; de Andrade AL. *Lancet*. 1996;348:1407; Bern C, et al. *Clin Microbiol Rev*. 2011;24:655; LeLoup G, et al. *Curr Opin Infect Dis*. 2011;24:428). Congenital transmission of Chagas disease occurs in 1–10% of children born to infected mothers. The safety of antitrypanosomal drugs in pregnancy is unknown. The treatment of mothers after delivery and cessation of breastfeeding is recommended (MMWR Morb Mortal Wkly Rep. 2012;61:477; Carlier Y, et al. *PLoS Negl Trop Dis*. 2011;5:e1250).

2. Benznidazole should be taken with meals to minimize gastrointestinal adverse effects. It is contraindicated during pregnancy.

3. Blum JA, et al. *Eur J Clin Microbiol Infect Dis*. 2012; Malvy D, Chappuis F. *Clin Microbiol Infect*. 2011;17:986.

4. Pentamidine and suramin have equal efficacy, but pentamidine is better tolerated.

5. Not FDA approved for this indication.

6. In one study, eflornithine for 7 d combined with nifurtimox × 10 d was more effective and less toxic than eflornithine × 14 d (Priotto F, et al. *Lancet*. 2009;374:56).

7. Eflornithine is highly effective in *T. b. gambiense*, but not in *T. b. rhodesiense* infections. In two studies of treatment of central nervous system disease due to *T. b. gambiense*, there were fewer serious complications with eflornithine than with melarsoprol (Kennedy PG. *Ann Neurol*. 2008;64:116; Chappuis F, et al. *Clin Infect Dis*. 2005;41:748). Eflornithine is available in limited supply only from the World Health Organization.

8. Kuepfer I, et al. *PLoS Negl Trop Dis*. 2012;6:e1695. Corticosteroids have been used to prevent arsenical encephalopathy (Pepin J, et al. *Trans R Soc Trop Med Hyg*. 1995;89:92).

Visceral Larva Migrans¹ (*Toxocariasis*)

	Drug	Adult Dosage	Pediatric Dosage
Drug of choice:	Albendazole ^{2,3}	400 mg PO bid × 5 d	400 mg PO bid × 5 d
Or	Mebendazole ²	100–200 mg PO bid × 5 d	100–200 mg PO bid × 5 d

1. Optimum duration of therapy is not known; some *Medical Letter* consultants would treat × 20 d. For severe symptoms or eye involvement, treatment is extended 2–4 weeks and corticosteroids can be used in addition (Rubinsky-Elefant G, et al. *Ann Trop Parasitol*. 2010;104:3; Turrientes MC, et al. *Emerg Infect Dis*. 2011;17:1263).

2. Not FDA approved for this indication.

3. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

Whipworm

See [Trichuriasis](#)

Wuchereria bancrofti

See [Filariasis](#)

There has been considerable clinical interest and basic science research into the functional mechanisms of the immune response and the identification of the specific biologic factors that modulate this response. This research has established that a critical and delicate balance in the regulation of both cellular and humoral function is essential for complete immunologic response to invasive pathogens and that alteration of this regulation may have potential clinical significance. Attempts to augment immune function in the challenged host or during specific immunodeficiency states have focused on numerous modifiers of immune biologic response. There are thousands of citations in the peer-reviewed medical literature on this topic. These efforts, in combination with advances made in hybridoma, recombinant DNA technology, nanotechnology, and proteomics, have resulted in numerous clinical trials conducted to explore the therapeutic utility of immunomodulating agents in the treatment of specific human disease states.⁶⁷ Select biologic agents used to manipulate immune regulation for the prevention and management of infectious diseases in infants and children are discussed.

MONOCLONAL ANTIBODIES

The use of serum antibody therapy, in the late 1800s, was among the first clinical attempts to modulate the immune response in the treatment of human sepsis. By the middle 1930s, serum-based therapy was the standard of care for many infectious illnesses, particularly pneumonia. Controlled trials during that time demonstrated that the administration of type-specific pneumococcal serum reduced the mortality rate by 50% in patients with pneumococcal pneumonia.^{62, 61,103} With the introduction of antimicrobial pharmacologic agents in the 1940s, the use of serum antibody therapy for sepsis became less popular. The development of hybridoma technology by Kohler and Milstein¹⁸⁰ in 1975, however, provided the means to generate virtually unlimited amounts of monoclonal antibodies for potential clinical use. This technology, in combination with the advances in recombinant DNA technology, has allowed researchers to generate highly specific human monoclonal antibodies and to humanize murine monoclonal antibodies.^{41,345} Monoclonal antibodies now are considered attractive molecules to be used potentially as antimicrobial and antiviral agents and immunomodulators, to deliver pharmacologic substances to sites of inflammation, or even to target certain cancerous tissues. This advance has led to the development of monoclonal antibody-based therapies to treat sepsis, septic shock, hemolytic uremic syndrome (HUS), viral diseases, and a number of inflammatory diseases in infants, children, and adults.

Monoclonal Antibody Preparations in Sepsis and Bacterial Infections

A monoclonal antibody could, in theory, be generated that would alter the clinical course of any infectious or inflammatory disease state. This hypothesis has fostered numerous studies evaluating the use of monoclonal antibodies in a variety of clinical diseases, particularly those related to alloimmune and autoimmune phenomena.^{75,93,133,211,272} The use of monoclonal antibodies to alter the pathogenesis of sepsis and septic shock also has received considerable experimental and clinical attention. These efforts have focused on two phases in the development of the septic shock syndrome: (1) to block bacteria and their components that induce shock and (2) to modify the release and action of the proinflammatory mediators that lead to septic shock. Other efforts to alter the pathogenesis of bacterial infections have focused on targeting specific bacterial virulence factors, by using passive immunization strategies for potential use in alternative treatment regimens.^{11,87,137,290} Here, we discuss

the use of monoclonal antibody therapy in neonatal sepsis, followed by passive immune strategies in *Pseudomonas* infections.

Monoclonal antibody preparations to block bacteria or their components in the development of septic shock were initially used in early studies using type-specific antisera against *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*.⁶² Attempts using monoclonal antibody therapy to alter the pathogenesis of bacterial sepsis leading to septic shock have focused on group B streptococcus (GBS) and *Escherichia coli*. These two bacteria are significant causes of neonatal morbidity and mortality. Infants usually acquire these bacterial infections from exposure in the birth canal; however, only a few of the exposed infants actually develop bacterial sepsis. Factors predisposing infants to acquisition of infection with these organisms include prematurity, prolonged rupture of membranes, and maternal sepsis. Neonatal infections occur more commonly with bacteria that possess specific capsular polysaccharides (i.e., the type III polysaccharide of GBS or the K-1 capsule of *E. coli*). Bacteria bearing these capsules are able to avoid opsonization and subsequent phagocytic killing by polymorphonuclear leukocytes (PMNs). Neonates with deficiencies of type-specific antibodies to these bacterial capsular antigens as a result of prematurity, which contributes to decreased maternal transplacental antibody transport, or inadequate maternal stores are predisposed to acquisition of GBS and *E. coli* infections.¹⁴⁷ These observations led investigators to hypothesize that passive antibody administration may be beneficial in preventing or reducing neonatal morbidity and mortality observed with these bacterial infections.

Rebecca Lancefield in 1933 originally demonstrated a protective efficacy for GBS antibody therapy using rabbit antisera. She established that this protective efficacy is type specific and classified three types of GBS strains. Antisera raised against type II or type III GBS did not protect against infection with type I bacteria. These experiments also suggested that antibodies to group B non-type-specific determinants (i.e., expressed on all GBS bacteria) are not protective.^{113,197,195,196} Further experiments by Lancefield and coworkers with type I GBS demonstrated that antibodies to both carbohydrate and protein capsular components can be protective.^{197,195} The first human studies to suggest that the administration of antibody to the infecting strain of bacteria could improve survival rates from early-onset GBS in infants occurred in the middle 1970s.^{300,302,303,305} In these studies, fresh whole blood either containing or lacking opsonic antibody was administered to infants with early-onset GBS disease. All nine infants who demonstrated a rise in opsonic antibody after transfusion survived. In contrast, three of the six infants (50%) who received blood lacking antibody to their infection strain died.³⁰⁰ Subsequent studies suggested that intravenous immune globulin (IVIG) could offer some protection against GBS infections in experimental animal models.^{106,152} Because of their lack of specificity and decreased opsonic activity, however, polyclonal-type IVIG antibody preparations have had only variable and limited ability to alter the course and outcome of GBS or other bacterial infections in clinical trials.¹⁴³

More recently, the International Neonatal Immunotherapy Study Collaborative Group conducted a randomized controlled trial of neonates with proven or suspected infection, which included 3493 infants receiving antibiotics, assigned to either polyvalent immunoglobulin G (IgG) immune globulin or placebo.⁴² There was no significant difference in primary outcome, which was death or major disability at 2 years.⁴² A Cochrane database meta-analysis of 9 studies (including the International Neonatal Immunotherapy Study) with 3973 infants with suspected or proven infection found no reduction in mortality rates during hospital stay, or death or major disability at 2 years.²⁵⁷ In subgroup analysis, no decrease in mortality during hospital stay was found following

IgM-enriched IVIG administration in 4 studies of 266 neonates.²⁵⁷ Routine use of IVIG or IgM-enriched IVIG is currently not recommended to prevent sepsis-related mortality in neonates.

The development of monoclonal antibodies to GBS type III occurred in the early 1980s.^{301–303,305} The GBS type III-specific antibodies, which were of the IgM class, protected rats against intraperitoneal infection with homologous type GBS. Survival rates were 95% to 100% for rats protected by monoclonal antibody compared with 17% for unprotected rats. Protection was afforded even when therapy was delayed up to 24 hours after inoculation. Antibody administration resulted in the rapid accumulation of PMNs at the site of infection and prevented the depletion of bone marrow granulocyte stores commonly seen in animal models and human neonates with GBS infection.³⁰² Monoclonal IgG and IgA antibody preparations also have been generated to type III GBS.^{30,243,301} A protective effect in animal models of GBS infection for all three immunoglobulin isotypes has been established.³⁰³ In GBS infections, the ability of an antibody isotype preparation to activate the complement system is related directly to its protective and opsonic activity.³⁰⁵ IgM is much more active in triggering complement than are monoclonal IgG and IgA preparations,^{199,305} a finding that may explain why monoclonal IgM is quantitatively more effective against GBS infections.^{146,149,305} Although human monoclonal IgM antibodies to GBS are available and have demonstrated effectiveness in reducing mortality in animal models of GBS sepsis, they have yet to be tried clinically to prevent or to attenuate GBS sepsis and septic shock in human neonates.^{275,305}

Concomitant with the studies of monoclonal antibody preparations for use in experimental models of GBS infections were similar studies using monoclonal preparations in *E. coli* sepsis. *E. coli* is an antigenically complex, gram-negative bacterium having more than 150 somatic (O) and 100 capsular (K) antigens. Several factors associated with *E. coli* have been implicated as contributing to the virulence of these organisms. Among these, the K-1 capsular polysaccharide and lipopolysaccharide (LPS) have received the most attention.³⁵ The K-1 capsular polysaccharide on *E. coli* as a contributing factor to the virulence of this organism was suggested first by Robbins and colleagues in 1974.²⁸² Subsequent studies established that *E. coli* strains that possess the K-1 capsular polysaccharide are resistant to opsonization through the alternative complement pathway.^{37,312} Several investigators have shown that antibody preparations to the K-1 capsular polysaccharide are opsonic and protective against lethal *E. coli* bacteremia in animals.³⁶ Although protection has been demonstrated primarily with IgM antibody, polyclonal hyperimmune IgG has shown some protection in animal models of lethal *E. coli* sepsis.²⁷⁴ Because the serum from neonates is deficient in opsonic activity for *E. coli*, some investigators suggested that the administration of antibody against *E. coli* K-1 would enhance neonatal resistance to infections with this organism.^{38,73} Investigators since have developed murine and human monoclonal IgM antibodies to *E. coli* K-1 and demonstrated that these antibodies are opsonic and protective against lethal *E. coli* infections in animal models.²⁷⁴

Other efforts have targeted Shiga-like toxin (Stx) producing *E. coli* (STEC), which is commonly produced by *E. coli* strain O157:H7. STEC is associated with HUS, which causes microangiopathic hemolytic anemia and is a leading cause of renal failure in children. There are two main Shiga-like toxins, Stx1 and Stx2, which pass across the inflamed colonic mucosa in infection and bind to target glycoprotein receptors in the kidney, thereby damaging the endothelium and resulting in platelet aggregation and microthrombosis.²⁷⁰ HUS usually results from infection with Stx2-producing *E. coli*. Neutralizing antibodies to Stx2 are currently under investigation. A phase I clinical trial showed urtoxazumab, a humanized IgG1 monoclonal antibody targeting Stx2, to be well-tolerated in adults and STEC-infected pediatric patients.²¹³ An earlier study of STEC-infected mice showed 100% survival when urtoxazumab was administered within 24 hours, but the agent was ineffective when administered at 48 hours, at which point Stx production had already reached its peak.³⁴⁷ Single-domain antibodies, such as those produced by the camelid family, comprise a novel type of monoclonal antibody preparation engineered to be just as specific as conventional antibodies, but offering several advantages lending to ease of manufacture, including increased permeability and a much smaller size (12–16 kDa) because they are composed of only a single domain. Mejias and colleagues²³⁴

demonstrated that camelid single-agent antibodies, composed of a single heavy-chain variable domain (VHH), were capable of neutralizing Stx2 at nanomolar concentrations in STEC-infected mice *in vivo*, with 0.05 pmol required to protect 80% of naïve weaned mice challenged with 4×10^{11} CFU/kg of Stx2-producing *E. coli* O157:H7.²³⁴ Because antibiotic treatment is not recommended in STEC infection, these alternative treatment modalities warrant further study and may show some promise in the treatment or prevention of HUS.

Staphylococci are major causes of acquired infections in prematurely born infants. Antibiotic resistance among staphylococcal species in these immunocompromised patients is of significant concern. Numerous monoclonal antibody-based preparations targeting staphylococcal virulence factors have been proposed. Pagibaximab, a humanized mouse chimeric monoclonal antibody targeting lipoteichoic acid (LTA) in gram-positive bacteria, has been evaluated in multiple clinical trials for the prevention of staphylococcal sepsis in very-low-birth-weight (VLBW) neonates.^{334,333} Phase I/II trials showed pagibaximab to be safe and efficacious, but a phase IIb/III trial failed to show a reduction in sepsis in VLBW neonates.^{8,265} A Cochrane data base review of 2 randomized controlled trials, assessing INH A-21 (a high-titer antistaphylococcal antibody IVIG preparation) in 512 and 1983 neonates, respectively, found no significant reduction in the risk of staphylococcal infection between INH A-21 and placebo.²⁹⁹ This same review found no significant difference in the risk of infection for Altastaph (a polyclonal, pooled immune globulin to type 5 and 8 capsular polysaccharide) as compared with placebo in 206 VLBW neonates.²⁹⁹

During the past several decades, the importance of pneumococcal vaccination for individuals at risk for acquiring infection has been underscored by the emergence of antibiotic resistance among pneumococcal strains and the increased prevalence of invasive pneumococcal disease in immunocompromised patients. Unfortunately, pure pneumococcal capsular polysaccharide vaccines are poorly immunogenic in many immunodeficient patients who are at risk for acquiring infection. This concern has led to the development of monoclonal antibodies against type-specific pneumococcal infections. A human monoclonal IgM antibody has been generated and shown to provide type-specific protection against lethal pneumococcal infections in mice, even in the presence of complement deficiency.³⁵¹ Thus, type-specific monoclonal antibody preparations likely could provide protection against pneumococcal infection in high-risk immunocompromised humans, if such preparations can be safely administered intravenously in humans.

Gram-negative bacteria comprise an important cause of multidrug-resistant infections in pediatric intensive care units.³⁴⁶ Alternative treatment regimens are needed to help combat drug-resistant bacterial strains, particularly *Pseudomonas* infections. *Pseudomonas aeruginosa* is an important cause of opportunistic and nosocomial infections, particularly in critically ill and immunocompromised patients, and it carries both a high mortality rate and a high likelihood for multidrug resistance. *P. aeruginosa* is a gram-negative bacillus that is distinguished from the Enterobacteriaceae by the production of oxidase. *P. aeruginosa* contains LPS in the outer membrane, along with relatively impermeable porins that, combined with multidrug efflux pumps, confer considerable resistance to many antimicrobial agents. Flagella, pili, and a mucoid exopolysaccharide slime layer facilitate binding of *P. aeruginosa* to host epithelial cells. Other virulence factors produced by *P. aeruginosa* include exotoxin A and exoenzyme S, which are injected into host cells by using a type III injection secretion system.

Studies have evaluated the use of monoclonal antibody therapy to treat *P. aeruginosa* infections in critically ill patients. A multicenter, phase II randomized, double-blind, placebo-controlled trial assessed the use of KB001, an anti-PcrV PEGylated (polyethylene glycol-linked) monoclonal antibody fragment, in mechanically ventilated patients with pulmonary *Pseudomonas* colonization.¹¹² KB001 is an engineered, human Fab fragment that binds to PcrV, which is a component of the type III secretory (TTS) apparatus (also known as the injectisome), that gram-negative bacteria including *Pseudomonas* use to inject TTS toxins directly into adjacent host eukaryotic cells.²⁹⁰ This results in cytotoxic injury and is proposed to contribute to acute lung injury. In this multicenter phase II study, Francois and colleagues¹¹² demonstrated that intravenous infusion of KB001 was well tolerated at 3 and 10 mg/kg compared with

placebo, and it was readily detected up to the 28-day end point. Although the study did not achieve clinical significance, KB001-treated patients had fewer episodes of *Pseudomonas* pneumonia and more 28-day *Pseudomonas*-free survivors.¹¹² KB001 was also evaluated in patients with chronic cystic fibrosis who received a single intravenous dose at 3 or 10 mg/kg. At 28 days, there was no significant decrease in symptoms, pulmonary function test results, or sputum culture *Pseudomonas* density; however, there was a dose-dependent decrease in sputum markers of inflammation, including myeloperoxidase, interleukin-1 (IL-1), and IL-8, with significant reduction in neutrophil elastase and sputum neutrophil counts.²³⁷ Monoclonal antibodies targeting the LPS-O polysaccharide moiety of *P. aeruginosa* and Psl, an exopolysaccharide involved in biofilm formation, have also been investigated.^{87,137} Moreover, a monoclonal biphasic antibody targeting both PcrV and Psl, BiS4 α Pa, has been described.¹³⁷ Another passive immune approach to *Pseudomonas* infections is the use of IVIG, which has been shown to improve bacteremia and acute lung injury significantly in mice, either prophylactically or 3 hours after bacterial inoculation, in concordance with measurable anti-PcrV titers in the IVIG.³⁰⁴ This study showed that although IVIG had no bactericidal activity in vitro, the addition of ceftazidime did, thus resulting in release of higher levels of TNF- α and increased mortality in the mice.

Monoclonal Antibody Therapy for Viral Infections

Monoclonal antibodies directed against viral glycoprotein complexes or that immunomodulate through other mechanisms are also being developed and evaluated for human use for a variety of viral diseases. Palivizumab, a humanized F protein monoclonal antibody, is routinely administered to preterm infants and other high-risk infants for immunoprophylaxis against respiratory syncytial virus (RSV) infection and disease.^{10,39} It also is used for prophylaxis against RSV infection in older high-risk subjects, such as transplant recipients and children with cystic fibrosis.^{10,39} In addition, palivizumab is administered in some patients to treat established RSV infections in immunocompromised patients awaiting immune reconstitution. A recombinant human antirabies monoclonal antibody has been tested in India. It appears to be safe and as efficacious as conventional serum-derived rabies immune globulin (RIG) and may soon replace the use of RIG for postexposure prophylaxis.^{122,245,246} Monoclonal antibodies directed against vaccinia virus have been developed and tested in preclinical animal models as potential therapeutic antibodies for treatment of smallpox,⁷² especially in viral glycoprotein complexes. The antiangiogenic monoclonal antibody bevacizumab (Avastin) is also been used to treat recurrent respiratory papillomatosis.²⁶

Cytomegalovirus (CMV) is a ubiquitous virus that is often asymptomatic in the immunocompetent host, but it may cause significant morbidity and mortality in immunocompromised persons and life-threatening congenital infections or long-term disability including hearing loss and intellectual disability when acquired by the fetus in utero from mothers with primary CMV infection. CMV glycoproteins (gB, gH/gL/gO, and gM/gN) mediate viral entry into fibroblasts, whereas a pentameric complex (gH/gL/UL128-131) is required for viral entry into epithelial cells, endothelial cells, and macrophages.¹¹¹ These glycoprotein complexes are important potential targets for therapeutic neutralizing antibodies. The mechanism by which CMV crosses the placenta and infects the fetus is incompletely understood, but the process likely occurs when CMV bound by low affinity, IgG anti-CMV gB antibodies binds the neonatal Fc receptor expressed by syncytiotrophoblasts (normally used for transcytosis of maternal IgG for passive immunity), resulting in transcytosis of IgG-virion complexes, followed by focal infection of cytotrophoblasts, and spread of infection to stromal fibroblasts, villous capillary endothelial cells, and leukocytes in the fetal compartment.²²¹ This process is in contrast to high-affinity binding of CMV by IgG anti-CMV gB antibodies that is known to be required to prevent fetal transmission, presumably because the high-affinity antibody remains bound to the virus following transcytosis into syncytiotrophoblasts, thereby preventing infection of the cytotrophoblasts and stromal fibroblasts.^{171,221}

Passive immunization with monoclonal antibodies and hyperimmune globulin (HIG) is currently being investigated for the prevention of

CMV transmission in pregnant women. A phase II trial, evaluating therapy with HIG in women with primary CMV infection, showed a small (but not statistically significant) decrease in the risk of fetal transmission of CMV in 61 women who received HIG (30% transmission; 18 fetuses or infants), compared with 62 women with primary CMV infection who received placebo (44% transmission; 18 fetuses or infants; $P = .13$).²⁷⁸ Fouts and associates¹¹¹ demonstrated, through serial depletions on CMV antigen expressing cells, that the major neutralizing component in HIG preventing epithelial cell entry is antibody directed against a pentameric complex gH/gL/UL128/UL130/UL131, and the dominant component preventing fibroblast entry is antibody against gH/gL. Lilleri and colleagues²¹⁰ investigated the presence of neutralizing antibodies in pregnant women with primary CMV infection and found that titers of IgG antibodies to the pentameric complex gH/gL/UL128-131 and gH/gL appeared earlier and were significantly higher in women who did not transmit the CMV virus to the fetus (nontransmitters) compared with women who did (transmitters).²¹⁰ Serum absorption of antipentameric antibodies with a soluble pentameric complex abolished the ability of the sera of CMV-infected women to neutralize viral infection of epithelial cells. This finding indicates that maternal antibodies to the pentameric complex play an important protective role against maternal-fetal transmission of CMV and are thus attractive targets for the development of passive immunization strategies. RG7667, a combination of two neutralizing monoclonal antibodies (MCMV5322A: anti-gH/gL; and MCMV3068A: anti-gH/gL/UL128-131), was evaluated in a phase I trial; this combination was shown to block CMV cell entry in fibroblasts, epithelial cells, endothelial cells, and macrophages and was safe and well tolerated in healthy adults.¹⁶²

Researchers have examined the possible blockade of the proinflammatory cascade that accompanies severe infections.^{1,20,117,194} The experimental attempts using monoclonal antibodies to modify the release and action of the proinflammatory mediators that lead to septic shock have focused on the proinflammatory effects of the cytokine family, endotoxin, and the functions of neutrophils and complement. Eculizumab (Soliris), a humanized monoclonal anti-C5 complement antibody that prevents the activation of terminal complement pathway, was approved by the US Food and Drug Administration (FDA) for treatment of atypical HUS and paroxysmal nocturnal hemoglobinuria.^{261,320} The safety profile of eculizumab remains unclear, however, with rare reports of *Aspergillus niger* peritonitis³²⁵ and meningococcal disease¹⁰¹ in adults. Meningococcal bacteremia and elevated liver function test results have been reported in the pediatric population.²⁶¹ Nonetheless, case reports have shown eculizumab to be an effective treatment in atypical HUS.²⁶¹ Eculizumab is not indicated in the treatment of STEC-related HUS.

Treatment with monoclonal antibodies, such as rituximab, an antiCD20 therapeutic monoclonal antibody, and infliximab, an anti-tumor necrosis factor- α (TNF- α) monoclonal antibody, in patients with immune disorders increases the risk for certain infections, such as nontuberculous mycobacteria, as well as increased risk of malignancy including lymphoma.^{45,138,277} Rituximab also profoundly depresses B-lymphocyte number and may lead to profound, persisting hypogammaglobulinemia.

CYTOKINES

Lymphokines and Monokines

The cytokines are a family of small, soluble protein molecules responsible for cell-to-cell communication. They are produced by several cell types and play crucial roles in many biologic processes, including growth, inflammation, immunity, and hematopoiesis. During infection, genes for nearly all the cytokines are expressed. The biologic activity of the prototype cytokines, the lymphokines and monokines, include interleukins and TNF- α ; these molecules, along with the granulocyte colony-stimulating factors (G-CSFs), have received considerable attention as potential immunomodulatory agents. In response to pathogen invasion, these cytokines perform a complex series of interactions to initiate a cascade of biologic events resulting in the propagation and subsequent regulation of the inflammatory response, thereby leading to pathogen alienation while maintaining host preservation. Thus, the cytokine family, through a complex web of interactions, functions to initiate and then both to upregulate and downregulate the inflammatory response. On

the basis of their roles of either upregulating or downregulating immune responsiveness, the cytokines generally and historically have been classified as either proinflammatory or antiinflammatory molecules. Although many cytokines have the potential to perform dual functions, either directly or indirectly, their proinflammatory or antiinflammatory properties are of considerable basic science and clinical therapeutic interest.^{34,63,88,109,194,200,209,259}

Some prominent proinflammatory cytokines and their cellular sources are listed in Table 242.1. TNF- α and IL-1 generally are considered to be prominent early proinflammatory mediators. They induce gene expression of other proinflammatory cytokines, including IL-6 and IL-8, thereby leading to neutrophil activation, recruitment, and degranulation. TNF- α and IL-1 also activate a secondary cascade of inflammatory mediators, including arachidonic acid–derived prostaglandin I₂, thromboxane A₂, prostaglandin E₂, platelet-activating factor (PAF), and the complement system. The CSFs and IL-3 also are proinflammatory cytokines that induce bone marrow stem cell production of granulocytes and monocytes, in addition to activating neutrophils and inducing production of IL-1 and TNF- α .^{34,63,88,109,194,200,209,259}

Prominent among the antiinflammatory cytokines (Table 242.2) are IL-4, IL-10, IL-13, and transforming growth factor- β . These cytokines may block endotoxin induction of IL-1 and TNF- α and suppress lymphocyte and monocyte function. In addition, the IL-1 receptor

antagonist blocks the proinflammatory action of IL-1 by binding its receptor.^{34,63,88,109,194,200,209}

Considerable experimental and clinical interest has focused on the proinflammatory cytokines TNF- α and IL-1 as important early mediators in the pathogenesis of sepsis and septic shock syndrome. The basis for the potential therapeutic utility of these two cytokines in human disease states involves two clinically distinct hypotheses: (1) excessive cytokine production results in host immune injury, leading to severe shock; and (2) deficient cytokine production renders a host susceptible to infection by invasive pathogens.¹⁹⁴

The hypothesis that cytokine overproduction can lead to severe lethal shock is demonstrated in several animal models and is suggested in patients with overwhelming sepsis. The outer membranes of gram-negative bacteria contain LPSs or endotoxin, which induce the early proinflammatory cytokines TNF- α , IL-6, and IL-1. Although these cytokines may protect the host from infection, if they are expressed in excessive amounts, their effects can result in multiple organ failure and death. During severe sepsis, the levels of both TNF- α and IL-1 increase proportionately with the degree of hypotension and organ failure. The combination of these two cytokines can result in synergism over their individual effects by severalfold and can lead to lethal septic shock syndrome.^{50,51} In animal models of shock and gram-negative sepsis, TNF- α levels rise rapidly after injection of bacteria or endotoxin and

TABLE 242.1 Proinflammatory Cytokines

Cytokine	Function	Predominant Cell Source
Tumor necrosis factor- α	Stimulates interleukin-6 and colony-stimulating factors Depresses erythropoiesis, stimulates interleukin-8 and interleukin-9 Promotes tumor necrosis and endotoxic shock	Monocytes and macrophages
Interleukin-1	Stimulates proliferation and differentiation of T and B lymphocytes Stimulates T lymphocytes to produce interleukin-2 Promotes colony-stimulating factor, interleukin-8 and interleukin-9 production, and endotoxic shock	Macrophages, astrocytes, monocytes, fibroblasts, keratinocytes, B lymphocytes, corneal epithelium, and other cell types
Interleukin-2	Stimulates growth of T lymphocytes Stimulates B-lymphocyte and monocyte differentiation Increases cytotoxicity of T lymphocytes and natural killer cells	Activated T lymphocytes
Interleukin-3	Multipotential hematopoietic cell growth factor Stimulates early B and T lymphocytes Mast cell growth factor	Activated T lymphocytes, natural killer cells
Interleukin-5	Stimulates eosinophil formation and differentiation Augments T lymphocyte cytotoxicity and proliferation of B lymphocytes	T lymphocytes, mast cells
Interleukin-7	Supports growth of pre-B lymphocytes Stimulates T lymphocytes	B lymphocytes, bone marrow fibroblasts, monocytes
Interleukin-8	Stimulates neutrophil, monocyte, and lymphocyte activation chemotaxis	Monocytes
Interleukin-9	Stimulates neutrophil, monocyte, and lymphocyte activation chemotaxis Stimulates erythroid progenitors, helper T-lymphocyte growth factor	T lymphocytes
Interleukin-11	T-lymphocyte–dependent stimulator of B lymphocytes	Bone marrow fibroblasts
Interleukin-12	Stimulates helper T-lymphocyte differentiation and interleukin-2 production Stimulates interferon- γ production Increases cytotoxicity of natural killer cells	T and B lymphocytes, lymphoblastoid cells
Interleukin-14	Stimulates proliferation of activated B lymphocytes Inhibits immunoglobulin secretion from B lymphocytes	T lymphocytes
Interleukin-15	Stimulates T-lymphocyte function and proliferation Enhances natural killer cell function	Monocytes and macrophages
Interleukin-16	Promotes migration of T lymphocytes	T lymphocytes
Interleukin-17	Stimulates interleukin-6 and interleukin-8 production	T lymphocytes
Interleukin-18	Stimulates interferon- γ and tumor necrosis factor- α production	Macrophages, mononuclear cells, and dendritic cells
Granulocyte colony-stimulating factor	Stimulates neutrophil colony formation	Monocytes and fibroblasts
Granulocyte-macrophage colony-stimulating factor	Stimulates granulocyte and monocyte formation Induces tumor necrosis factor	T lymphocytes, natural killer cells, endothelial cells, fibroblasts, and keratinocytes
Macrophage colony-stimulating factor	Activates monocytes and granulocytes Stimulates macrophage colony formation Induces interleukin-1 and tumor necrosis factor	Fibroblasts, monocytes, and endothelial cells

TABLE 242.2 Antiinflammatory Cytokines

Cytokine	Function	Predominant Cell Source
Interleukin-4	Stimulates proliferation of T and B lymphocytes and megakaryocytes A growth factor for mast cells and erythroid precursors	T lymphocytes
Interleukin-6	Blocks endotoxin induction of interleukin-1 and tumor necrosis factor B- and T-lymphocyte-stimulating activity	Monocytes, T and B lymphocytes, fibroblasts, epithelial and endothelial cells
Interleukin-10	Blocks production of interleukin-1 and tumor necrosis factor Inhibits primary allogeneic T-lymphocyte responses Inhibits interleukin-2, interleukin-8, and granulocyte-macrophage colony-stimulating factor	T and B lymphocytes, macrophages and monocytes
Interleukin-13	Blocks production of interleukin-1, tumor necrosis factor, and interleukin-8 Suppresses nitric oxide formation	T lymphocytes
Interleukin-1 receptor antagonist	Binds interleukin-1 receptors, blocking interleukin-1 effects	Monocytes and macrophages
Transforming growth factor- β	Reduces endotoxin-induced interleukin-1 and tumor necrosis factor production	Monocytes and macrophages

reach peak concentrations at 60 to 90 minutes, whereas IL-1 levels rise more slowly, peaking at 180 minutes. A similar time course response has been observed in human subjects injected with endotoxin.^{51,236} Children with septicemia and purpura fulminans and children with meningococcal disease demonstrated an association between morbidity and mortality and high serum levels of TNF- α and IL-1.^{119,245} These studies and others implicate TNF- α and IL-1 as prominent modulators in the development of the septic shock syndrome and suggest that a potential therapeutic benefit may be obtained by inhibiting the production of these cytokines and reducing their proinflammatory effects.

Experimental attempts to attenuate the excessive proinflammatory cytokine activity of TNF- α and IL-1 have focused on (1) inhibiting release of endotoxin, (2) blocking endotoxin–target cell binding and preventing the transmembrane signaling mechanisms leading to production of TNF- α and IL-1, (3) controlling the synthesis of TNF- α and IL-1 by inhibiting or suppressing specific cytokine gene transcription and translation, (4) inhibiting release of TNF- α and IL-1, (5) administering TNF- α and IL-1 neutralizing antibodies and soluble receptors, (6) producing and administering TNF- α and IL-1 receptor antagonists that block specific cytokine binding to target cell receptors, and (7) blocking TNF- α or IL-1 intracellular transmembrane signaling mechanisms and preventing their action on target cells.²⁰⁰

The use of monoclonal antiendotoxin antibodies to inhibit the binding of endotoxin to its target cells has received considerable attention. Numerous in vitro and in vivo animal experiments have suggested that blocking of endotoxin leads to improved survival by inhibiting proinflammatory cytokine production and expression.²⁴⁷ The initial clinical studies in patients with gram-negative bacteremia who were treated with immunoglobulin preparations directed against endotoxin demonstrated a significant reduction in mortality rates.^{21,293} Further studies suggested a reduction of septic shock in similarly treated high-risk surgical patients.²¹ These observations led to the development of several clinical trials using human monoclonal antiendotoxin antibodies. HA-1A is a human monoclonal antibody against the lipid A moiety of bacterial endotoxin. The mechanism of HA-1A action is to block endotoxin triggering of the intracellular events leading to proinflammatory cytokine synthesis. In placebo-controlled clinical trials of HA-1A, either HA-1A or placebo was infused during the course of 20 minutes to patients with severe sepsis. These patients also received cardiopulmonary support and antibacterial therapy. The etiologic agents of sepsis included *E. coli*, *Pseudomonas*, and *Klebsiella* and *Enterobacter* spp. The investigators reported that HA-1A significantly reduced the incidence of mortality in adults with septic shock and gram-negative bacteremia. The mortality rate for those patients who were in severe shock before receiving HA-1A was reduced by 42%.³⁵² Although these early clinical studies using HA-1A were encouraging, a protective role for antiendotoxin antibodies was not established in subsequent clinical trials.^{161,216} Antiendotoxin therapy may be more effective if it is given earlier during the sepsis syndrome before the development of shock. Because bacterial lysis caused by antibiotics is an ongoing process and results in further release of

endotoxin, multiple doses of antiendotoxin antibodies also may prove beneficial in treating sepsis. The future clinical use of antiendotoxin antibodies may be in combination with other immunomodulation therapies, directed at simultaneously blocking several steps in both the propagation and action of proinflammatory cytokines.

Studies of cytokine inhibition have focused on controlling TNF- α and IL-1 with anti-TNF- α antibodies directed at these specific cytokines and their receptors. Control of proinflammatory cytokine synthesis is specific for each individual cytokine and requires an understanding of the unique temporal relationships among molecules during the propagation of inflammatory responses. A critical aspect of TNF- α and IL-1 gene expression in a variety of cell types has been the reported exquisite sensitivity of these cytokines to bacterial endotoxin.^{63,88,194,200} Human blood monocytes synthesize TNF- α and IL-1 in the presence of endotoxin. In the absence of endotoxin, however, gene expression occurs, but protein translation does not take place.²⁹⁴ Thus, these cells may be viewed as being primed for bacterial endotoxin exposure. TNF- α and IL-1 transcription is suppressed by the antiinflammatory cytokines IL-10, IL-13, and transforming growth factor- β , but the clinical therapeutic benefits these cytokines have in treating septic shock remain to be defined.^{65,139,239,295} Agents blocking the lipoxygenase pathway of arachidonate metabolism also have been implicated in the reduction of TNF- α and IL-1 synthesis, and corticosteroids have been shown to suppress both TNF- α and IL-1 transcription and synthesis, but only when they have been administered before transcription has been initiated.^{107,291}

The use of corticosteroids in infants and children with bacterial meningitis demonstrated that treatment with a combination of dexamethasone and antibiotics results in lower cerebrospinal fluid levels of TNF- α than occurs with treatment with placebo and antibiotics.²⁴⁵ In addition, patients treated with corticosteroids had fewer neurologic symptoms.¹⁷⁴ Subsequent multicenter trials, however, failed to establish a protective effect of corticosteroid use in the treatment of children with meningitis.³²⁷ One possible explanation for this discrepancy may be that corticosteroids almost exclusively suppress endotoxin-induced, proinflammatory cytokine gene transcription but have little or no effect on proinflammatory cytokine translation.^{88,307} Thus, some investigators have suggested that the early administration of corticosteroids, before transcription has been initiated, would block cytokine synthesis. Timing of corticosteroid administration therefore may account for some of the clinical variability seen with its use in children with meningitis. Clinical trials are focusing on TNF- α and IL-1 synthesis with the administration of corticosteroids either before or while antibiotics are administered. Similarly, the temporal use of antibiotics, corticosteroids, and antiendotoxin therapy may result in an additive therapeutic benefit.

Neutralizing monoclonal antibodies against murine or human TNF- α have been shown to decrease mortality rates in several experimental animal models of sepsis.^{27,225,319} Studies with soluble TNF- α receptors or their immunoadhesin constructs also have demonstrated an immunoprotective effect of TNF- α blockade in animal models of endotoxemia or bacteremia.²⁵ Although anti-TNF- α antibodies are being used with

caution in humans, anti-TNF- α treatment in a limited number of patients with established septic shock resulted in increased vascular hemodynamics and left ventricular stroke volume.¹³¹ The *in vitro* use of free soluble TNF- α receptors to bind TNF- α results in a 10- to 50-fold increase in binding affinity over that observed with anti-TNF- α monoclonal antibodies.¹³² Results from phase II clinical trials using soluble TNF- α receptors, however, have not shown improvement in survival rates; moreover, administration of high doses actually increased the incidence of mortality.^{132,288}

Certain naturally occurring substances inhibit IL-1 synthesis and action, but they also have effects on many of the other cytokines. Specific inhibitors of IL-1, however, have been identified. Most prominent of these is the IL-1 receptor inhibitor that competes with the binding of IL-1 to its cell surface receptor. Recombinant IL-1 receptor antagonist (IL-1ra) that blocks IL-1 effects has been studied in various animal models.^{4,256} For instance, IL-1ra prevents death from endotoxin shock in rabbits.²⁵⁶ The therapeutic use of IL-1ra in treating septic shock in early phase II human clinical trials showed improved survival rates at 28 days.¹⁰⁸ The subsequent randomized phase III trials, however, failed to show improvement in patients with severe shock.¹⁰⁷ Further clinical studies are ongoing. IL-1ra also has been used in treatment trials of patients with acute myelogenous leukemia. The uncontrolled production of IL-1 by leukemic blasts has been proposed to result in the continued proliferation of these cells and the development of acute myelogenous leukemia. Studies have shown that IL-1ra blocks the spontaneous proliferation and production of granulocyte-macrophage CSF (GM-CSF), IL-1, and IL-6 in the peripheral blood and bone marrow cells of these patients.²⁷⁶ The potential clinical use of IL-1ra is being investigated in patients with psoriasis, rheumatoid arthritis, and myelogenous leukemia.¹³⁴ Similarly, combination therapy with the simultaneous blockade of both TNF- α and IL-1 is being investigated in endotoxin models of shock and a number of clinical disease states.²⁸⁶

Another approach to attenuate excessive proinflammatory cytokine responses is the use of pharmacologic agents. Salyer and colleagues²⁸⁹ demonstrated that pentoxifylline, a methylxanthine derivative that blocks TNF- α transcription and production, could override some of the effects of TNF- α on PMNs. In this study, the profound decrease in human PMN chemotactic ability caused by excessive TNF- α was restored to normal by treatment with pentoxifylline. The specific mechanisms of this effect of pentoxifylline are not known, but the drug has been shown to restore PMN membrane fluidity inhibited by TNF- α that is critical for cell movement.^{252,254} Furthermore, pentoxifylline can block PMN adhesion to endothelium and result in decreased PMN respiratory burst activity, which is thought to be responsible for the improved survival rates seen in pentoxifylline-treated animal models of endotoxin-induced septic shock.²⁵⁸ Some of the clinical trials using pentoxifylline in surgical patients with early evidence of systemic inflammation have suggested a cardioprotective effect, although other studies have been less convincing.^{100,310} Pentoxifylline also has been evaluated in preterm infants with sepsis. A meta-analysis of 6 randomized controlled trials with 416 infants found that pentoxifylline used as adjuncts to antibiotics in neonates with sepsis decreased all-cause mortality (typical relative risk, 0.57; 95% confidence interval [CI], 0.35–0.93; typical risk difference, –0.08; 95% CI, –0.14 to –0.01; number needed to treat to benefit = 13; 95% CI, 7–100).²⁶² No adverse effects attributable to pentoxifylline were noted. Pentoxifylline did not change the risk of necrotizing enterocolitis (NEC) in neonates with sepsis. Amrinone, a phosphodiesterase inhibitor, also has been shown to reduce TNF- α levels in LPS-challenged mice.¹²⁰ Thus, these and other pharmacologic agents may be useful in preventing or reducing some of the adverse and even fatal effects that are mediated by proinflammatory cytokines.

IVIG may have a potential inhibitory effect on proinflammatory cytokine activity. Patients in the active phase of Kawasaki disease have increased levels of TNF- α and IL-1. These cytokines have been postulated to stimulate local inflammatory responses by regulating leukocyte adherence and activation, thereby leading to the vascular damage that is a critical clinical aspect of this disease. Another suggestion is that the effects of IVIG therapy in Kawasaki disease, and perhaps in other diseases, may result from the attenuating production of the proinflammatory cytokines TNF- α and IL-1.^{6,16,146} Animal models of LPS-induced TNF- α

and IL-1 synthesis demonstrate a suppression of mononuclear cell synthesis of these proinflammatory cytokines when they are treated with IVIG.¹⁸ The peripheral blood mononuclear cell production of TNF- α and IL-1, however, in patients with Kawasaki disease who were receiving IVIG therapy showed decreased synthesis of IL-1 but not of TNF- α .^{203,202} The role of IVIG as an immunomodulator has been suggested in an ever-growing number of clinical disease states because of its broad immunoregulatory potential.^{16,142} IVIG is indicated for the treatment of Kawasaki disease,²⁵¹ and it has also been used in the treatment of severe autoimmune neutropenia of infancy⁴⁹ and in cases of fetal and neonatal alloimmune thrombocytopenia.¹¹⁸

The hypothesis that diminished levels of cytokines may render a host susceptible to development of infection was introduced by Weatherstone and Rich.³³¹ They suggested that the increased susceptibility to infection observed in premature neonates may be secondary to deficient proinflammatory cytokine production. In their study, these investigators measured cord blood monocyte secretion of TNF- α and IL-1 with and without stimulation of LPS. IL-1 activity by LPS-stimulated preterm monocytes did not differ from that observed by LPS-stimulated adult monocytes. TNF- α activity, however, in the LPS-stimulated monocytes from preterm neonates was significantly lower than that in both stimulated and unstimulated adult monocytes. Thus, these investigators concluded that diminished production of TNF- α may predispose the preterm infant to acquisition of infection. This finding has not been supported by the studies of infected animals, which show markedly elevated TNF- α levels, and subsequent studies in preterm infants have not established a deficiency in TNF- α .³³⁹ Williams and colleagues³³⁹ and Peat and coworkers²⁶⁶ have, in contrast, shown that mononuclear cells from term neonates produced enhanced levels of TNF- α in response to GBS or endotoxin. Ongoing studies are defining the role of cytokine production in neonatal and other infections.

The proinflammatory cytokine IL-2 acts on activated T lymphocytes and to some extent on B lymphocytes and natural killer (NK) cells and causes them to proliferate or differentiate. IL-2 is synthesized by both T cells and NK cells.^{238,329} Decreased IL-2 production or IL-2 receptor expression has been noted in a number of clinical disease states, most notably in cases of severe combined immunodeficiency disease. Lesser degrees of abnormalities may occur in acquired immunodeficiency syndrome (AIDS), type 1 diabetes mellitus, systemic lupus erythematosus, and hypogammaglobulinemia.^{194,200,209} The most intriguing potential for IL-2 in the treatment of disease involves its use in tumor therapy.²⁸⁴ IL-2 currently is approved for the treatment of metastatic renal carcinoma. Use of IL-2-activated NK cells results in a decrease in tumor burden in approximately 20% of patients, although serious side effects occur. In addition to its potential role as an antitumor agent, IL-2 shares many of the same effects as interferon- γ (IFN- γ) and may someday function as a therapeutic agent in infection, autoimmunity, and immunodeficiency.^{200,284}

Both IL-8 and IL-9 have been investigated in various human disease states, primarily because of their powerful role in stimulating neutrophil function, including activation, adhesion, and chemotaxis. Patients with cystic fibrosis, bronchiectasis, and chronic bronchitis have demonstrated elevated levels of IL-8 in their sputum.²⁷⁹ The sputum from these patients is highly chemotactic to neutrophils, but with treatment with monoclonal antibodies to IL-8, this chemotactic effect was inhibited. Aerosolized IL-8 inhibitors have been used in patients with cystic fibrosis and have resulted in decreased inflammation in these patients.^{227,279} IL-8 inhibitors are being evaluated in infants with bronchopulmonary dysplasia. Researchers have speculated that the persistently elevated levels of IL-8 in the tracheal fluid of ventilated preterm infants lead to neutrophil accumulation and the development of pulmonary fibrosis, which may be reduced by IL-8 inhibitors.^{169,181} Similar studies are being conducted with IL-9 inhibitors. Thus, these cytokines may play an important role in the acute inflammatory response leading to chronic disease states, and blocking of this response may be of therapeutic benefit. The proinflammatory IL-5 has not been implicated in a specific human disease state, but its strong B-cell proliferative effects suggest that it has a possible role in the pathogenesis of immunodeficiency, and its potent effects on eosinophil production, activation, and migration implicate its action in allergic responses.⁴⁴

The proinflammatory activities of IL-12 and IL-18 are also of current immunologic interest. IL-12 is an integral immune regulator that is produced primarily by macrophages and dendritic cells.²⁵⁴ IL-12 has been shown to induce the production of IFN- γ by T cells and natural NK cells.^{219,220,254} IL-18 is another cytokine with many proinflammatory functions.²²⁹ IL-18 was defined initially as IFN- γ -inducing factor.^{52,89,201} IL-12 and IL-18, both alone and in synergy, regulate IFN- γ production in response to infection with intracellular parasites and bacteria and in certain autoimmune diseases.* The regulation of these cytokines may be therapeutically beneficial in certain disease states.^{95,127,224} The other proinflammatory cytokines also are in various developmental stages of experimental investigation. As we learn more about their specific actions, we will better be able to determine their use as potential immunomodulating agents.

The antiinflammatory cytokines have limited clinical use. IL-4 can block both IL-1 and TNF- α transcription.^{139,295} IL-4 has been shown to inhibit human neutrophil adhesion to human endothelial cells while enhancing the adhesion of eosinophils.²⁴² These effects have not been implicated in specific human diseases, but an IL-4 action is suggested in allergic responses. Although IL-6 has both antiinflammatory and proinflammatory effects, the levels of this cytokine were found to correlate with mortality rates in children with gram-negative and gram-positive sepsis, thereby suggesting that monitoring of IL-6 levels may be of prognostic value.³²³ Similarly, IL-10 has been shown to block production of IL-1, IL-6, IL-8, IL-12, and TNF- α , as well as GM-CSF, in animal models.^{78,222} IL-10 also has effects on mast cells, T cells, and NK cells, and it inhibits primary allogeneic T-cell responses. Thus, IL-10 may have a potential role in treating acute and chronic inflammation and may be effective in suppressing transplant rejection.^{22,78} Studies examining the safety and immunomodulatory effects of the intravenous injection of IL-10 in humans demonstrate that it is well tolerated and results in decreased production of both TNF- α and IL-1.³⁴ Additional clinical studies have been conducted on the potential immunoregulatory effects of the antiinflammatory cytokines and may indicate the therapeutic use of these agents in human disease states.

IL-17 is a proinflammatory cytokine implicated in the regulation of many inflammatory states. IL-17 is produced by several cell types, including activated T-cell subsets, NK cells, and neutrophils.^{91,212,314} IL-17 is involved in the regulation of inflammatory bowel disease and systemic lupus erythematosus.¹⁸³ IL-17 production is markedly deficient in patients with autosomal dominant hyper-IgE (Job syndrome) who have neutrophil chemotactic defects and recurrent bacterial and candidal infections.¹⁹³ More recently, decreased intracellular and extracellular production of IL-17 by cord blood mononuclear cells suggested that IL-17 may contribute to the human neonates' increased susceptibility to microbial infections.^{59,60} Furthermore, the addition of IL-17 to cord blood mixed mononuclear cells significantly enhances production of the proinflammatory cytokines IL-6, TNF- α , IL-1 β , and IL-8 in response to GBS.^{59,60} IL-23 promotes the development and survival of IL-17-producing cells. The IL-17/IL-23 axis has been implicated in mediating initial neutrophil responses during infection. Dysregulation of this pathway is suggested in autoimmune diseases (i.e., multiple sclerosis, Crohn disease, and rheumatoid arthritis).^{91,92,313} IL-17/IL-23 levels are elevated in patients with systemic lupus erythematosus and correlate with symptoms.^{207,344,348} Current efforts are under investigation to modulate the IL-17/IL-23 axis to regulate autoimmunity and inflammation.¹⁷⁵ In a phase III randomized controlled trial of treatment with the anti-IL-17A monoclonal antibody, secukinumab (Cosentyx), in 397 patients with psoriatic arthritis,¹⁵ patients were assigned to 300 mg, 150 mg, or 75 mg subcutaneous secukinumab or placebo.¹⁵ Subcutaneous secukinumab at 300- and 150-mg doses significantly improved the signs and symptoms of psoriasis, defined as at least 20% improvement in the American College of Rheumatology response criteria (ACR20). Common adverse outcomes included respiratory infections and nasopharyngitis. Secukinumab is now approved by the FDA for use in the treatment of moderate to severe plaque psoriasis in adults. Ustekinumab (Stelara), a monoclonal antibody to the shared p40 subunit of IL-12 and IL-23, is also FDA approved for the treatment of treatment of moderate to severe plaque

psoriasis in adults, after the agent was shown to be effective in achieving at least ACR20 at 24 weeks, with continued benefit at 52 weeks.²⁸¹ Brodalumab, a monoclonal antibody to the IL-17A receptor, has also been shown to be effective for the treatment of psoriasis in clinical trials, and was approved by the FDA in February 2017, despite termination of the Study of Efficacy and Safety of Brodalumab Compared With Placebo and Ustekinumab in Moderate to Severe Plaque Psoriasis Subjects (AMAGINE) phase III trials after two suicides were reported, with lingering uncertainty regarding reports of suicidal ideation.^{79,233}

The removal of cytokines from blood of septic patients has received attention. The continuous removal of cytokines in the systemic inflammatory response syndrome by hemofiltration and hemodialysis is currently being used.³⁴⁸ Cytokine adsorption has also received attention. CytoSorb, a hemoadsorption system, has been reported to decrease proinflammatory marker concentrations and significantly reduce supportive vasopressor requirements in patients with septic shock¹⁵³ and cardiogenic shock.⁴⁶ A randomized controlled trial in 43 patients with septic shock and acute lung injury showed that CytoSorb was safe and significantly reduced IL-6 concentrations compared with controls.²⁹² A randomized controlled trial in patients undergoing cardiopulmonary bypass (CPB), however, did not show a significant reduction in proinflammatory cytokine concentrations following hemoadsorption.²³ CPB has been shown to trigger proinflammatory cytokine production in an unpredictable manner because of contact activation of blood and white blood cells by artificial surfaces in the extracorporeal circuit.⁸² The lack of significant IL-6 production found by Bernardi and colleagues²³ may be attributable to the much shorter duration of CPB (191 ± 56 minutes) than in patients in prior case reports (4 hours to 4 days), as the investigators point out in their study. An additional clinical trial evaluating the use of CytoSorb during CPB is currently under way.¹⁹ The use of synthetic polymer resins,¹⁷³ immobilized antibody systems,²⁵³ and activated carbon¹³ is also under investigation. The polymyxin B filtration system has been shown to protect mice from the endotoxin-induced shock,⁴⁷ and it is under investigation in adult patients with gram-negative sepsis in intensive care units.⁷⁴ These efforts to reduce the proinflammatory cytokine load may have a role in the treatment of septic shock.

Colony-Stimulating Factors

CSFs are involved principally in the production of neutrophils and monocytes. They were discovered because of their ability to stimulate the formation of colonies of granulocytes and monocyte-macrophages in cultured bone marrow cells and were named according to the primary cell colony type that they elicited. GM-CSF induces peripheral blood macrophages and granulocytes. It also has other pleiotropic effects, including stimulation of precursors of megakaryocytes, mast cells, and eosinophils. In addition, GM-CSF has effects on neutrophil migration and phagocytosis. G-CSF induces peripheral blood granulocytes. Its actions are on both the production and the function of neutrophils, including migration, phagocytosis, and superoxide generation. Macrophage CSF (M-CSF) induces peripheral mononuclear phagocytes. IL-3 increases mast cell populations, as well as the induction of granulocytes, macrophages, eosinophils, and megakaryocytes.^{90,91,130,191,201,208,235}

Clinical studies with GM-CSF and G-CSF as adjuvant therapy have been performed in individuals with distinct lymphopoietic disorders (i.e., congenital agranulocytosis, cyclic neutropenia, Shwachman-Diamond syndrome) or those disorders that are the consequences of cytotoxic chemotherapy, AIDS, and aplastic anemia. The CSFs can stimulate granulocyte and monocyte populations in these individuals, but the response is restricted to the number of available stem cells. CSF treatment can partially or completely reverse congenital neutropenia and has shown great promise in regeneration of lymphopoietic cells after administration of cytotoxic chemotherapy and high-dose chemotherapy followed by autologous bone marrow transplantation. Recombinant human GM-CSF (rhGM-CSF) also has been shown to be beneficial in patients with aplastic anemia.^{12,13,321} Hammond and colleagues¹³⁵ demonstrated a dramatic increase in neutrophil counts in children with cyclic neutropenia who were treated with recombinant human G-CSF (rhG-CSF). Cyclic neutropenia is a rare disorder characterized by regular, 21-day cyclic fluctuations in the number of blood neutrophils, monocytes, eosinophils, lymphocytes, platelets, and reticulocytes. Although the exact

*References 89, 95, 127, 150, 157, 172, 224, 255, 308, 313, 314, 324, 332, 349.

mechanism of this disorder is not known, it is attributed to a regulatory abnormality affecting proliferation of stem cells. These infants have recurrent aphthous stomatitis, pharyngitis, lymphadenopathy, fever, and numerous infections during the periods of neutropenia. The length of cycling in treated infants decreased from 21 days to 1 day, and the neutrophil turnover rate increased nearly fourfold, thus significantly reducing the frequency of infection. The use of rhG-CSF also has shown promise for infants and children with neutrophil production disorders. Infants with congenital agranulocytosis, Kostmann syndrome, and Shwachman-Diamond syndrome, disorders characterized by severe, persistent absolute neutropenia, show a dramatic increase in neutrophil count after treatment with rhG-CSF.³³ In addition, rhG-CSF and rhGM-CSF have been used in neutropenic patients with AIDS. Despite the concern that the effects of GM-CSF to activate macrophages may in turn promote replication of human immunodeficiency virus (HIV), current studies are defining the role of rhGM-CSF and rhG-CSF in patients with AIDS.^{129,208}

Thus, CSFs have emerged as significant modulators of human immune function and lymphopoiesis. Because the CSFs can functionally activate mature granulocytes and monocytes, considerable attention has focused on their future role in treating individuals at risk for acquiring infection. English and colleagues⁹⁴ reported decreased GM-CSF production by neonatal T cells. Because a major factor contributing to the increased susceptibility of human neonates to severe infections is their inability to produce adequate numbers of neutrophils in response to bacterial infections, these neonates may benefit from CSF treatment during severe infection.²⁹ Similar treatment in immunologically stressed patients with burns and trauma also may prove beneficial.^{77,250}

INTERFERONS

Interferon- α and Interferon- β

The IFNs are glycoproteins that were discovered because of their antiviral properties. They are known to possess antitumor and immunomodulatory activities in addition to their antiviral effects.¹⁷ The IFNs have been classified into three major groups: α , β , and γ . IFN- α and IFN- β were previously known as type I IFNs and have similar protein structures and bind the same receptor. IFN- γ , formerly type II IFN, has a much different structure and its own receptor.⁹ IFN- α is produced by leukocytes. The earliest demonstration of its clinical usefulness was in the treatment of AIDS-related Kaposi sarcoma. In these initial studies, a Kaposi sarcoma tumor response occurred in 30% to 50% of the patients treated with recombinant IFN- α .^{128,188,240,244} Researchers have speculated that IFN- α exerts its antitumor effect by activating cytotoxic T cells. Since then, placebo-controlled clinical trials have shown that IFN- α also may have significant antiretroviral effect in HIV-infected patients.^{186,198} Clinical trials have been conducted to determine the effect of early treatment with IFN- α in reducing progression of HIV disease and to determine the therapeutic effect of IFN- α in combination with other drugs in the treatment of HIV infection and HIV-related diseases.^{185,187}

IFN- α also has been used in various parts of the world for the treatment of chronic myeloid leukemia, hairy cell leukemia, basal cell carcinoma, multiple myeloma, hepatitis B and C, and condylomata acuminata (genital warts). In chronic myeloid leukemia, early treatment with IFN- α was reported to elicit complete hematologic remission in more than 70% of the patients treated. Many of these patients had total elimination of the Philadelphia chromosome, which is a hallmark of the disease.³¹⁵⁻³¹⁷ Complete to 80% remissions also have been reported in the treatment of hairy cell leukemia.²⁷³ Intraleisional injection of IFN- α into basal cell carcinoma of the skin resulted in 81% tumor remission, as determined by biopsy.^{70,164} Despite the variability of the outcomes among reports on the use of IFN- α in the treatment of multiple myeloma, it has been approved as therapy for these patients in a number of European countries.²²³

IFN- α also is used for the treatment of hepatitis B and C.²⁰¹ Clinical responses have been reported to be of long duration, often with complete loss of both hepatitis B surface antigen and evidence of viral replication. In chronic hepatitis C, complete responses to therapy, determined by the decline of serum aspartate aminotransferase to normal levels, have been observed in 50% to 70% of the patients treated. Although serum

aspartate aminotransferase levels in one-half of the patients who had improved returned to pretreatment levels within 6 to 12 months after discontinuation of therapy, nearly 20% achieved sustained remission.^{80,86,156,182,267} Studies also have shown that IFN- α is useful in treating condylomata acuminata caused by papillomaviruses.⁴³ Intraleisional injections of IFN- α completely eliminated warts in more than 50% of the patients treated. IFN- α therapy also is suggested to reduce the number of lesions in juvenile laryngeal papillomatosis after systemic use.²¹⁷ Thus, IFN- α has therapeutic potential as both an antitumor agent and an antiviral agent.

IFN- β also has received attention as an antiviral and antitumor agent. Its clinical usefulness as a single-agent therapy is suggested in relapsing multiple sclerosis. The mechanism of IFN- β therapeutic action in multiple sclerosis is unknown.¹⁶⁵ Ongoing studies are investigating IFN- β therapy in combination with IFN- α in the treatment of various malignant neoplasms.

Interferon- γ

IFN- γ is produced by CD4⁺ and CD8⁺ cells as well as by NK cells.¹⁴⁴ Investigators have reported that circulating mononuclear cells and T cells from neonates are markedly deficient in their ability to produce IFN- γ in response to a variety of stimuli, compared with adult cells.^{207,297,298,340} Studies using recombinant IFN- γ have shown that preincubation of neonatal neutrophils, which are deficient in their chemotactic ability, with recombinant IFN- γ enhances their chemotactic response to a level equal to that of adult neutrophils.¹²⁸ Other studies have shown that neonatal mixed mononuclear cells are deficient in the production of the IFN- γ -stimulating cytokines IL-12 and IL-18 in response to GBS.^{148,150,170} In vitro treatment with recombinant IL-12 and IL-18 can correct this defect in IFN- γ production in response to GBS. These findings suggest that a potential role exists for the regulation of IFN- γ in neonatal host defense.

Job syndrome was first described by Davis, Schaller, and Wedgwood⁸¹ in 1965 in two patients with recurrent staphylococcal abscesses. Patients with this syndrome often develop chronic sinopulmonary infections and mucocutaneous *Candida* infections. Hill and coworkers¹⁵¹ observed that the patients with Job syndrome also have a profound defect in neutrophil chemotactic responsiveness along with extreme hyper-IgE. This defect in neutrophil chemotaxis is intermittent and occurs predominantly when the patient is symptomatic.^{76,145,151} Because production of IFN- γ by mononuclear leukocytes in patients with hyper-IgE is markedly deficient or absent, in vitro studies were conducted to determine the effect of recombinant IFN- γ on the chemotactic responsiveness of neutrophils from patients with this syndrome. After pretreatment with IFN- γ , the chemotactic response of the neutrophils from patients with Job syndrome increased significantly, with an average enhancement of 300% above baseline to levels not significantly different from those of matched healthy controls.^{168,349} In four patients with Job syndrome, preliminary trials of IFN- γ therapy with hyper-IgE suggested clinical benefit in three of these patients, with a significant decrease in eczema as well as in pulmonary symptoms and secretions.

Patients with chronic granulomatous disease (CGD) have an inherited deficiency in the proteins required for nicotinamide adenine dinucleotide phosphate oxidase activity. Phagocytes with this enzymatic defect are able to engulf bacteria but cannot generate the respiratory burst necessary to kill the organisms. Consequently, patients with CGD suffer severe, chronic, recurrent, life-threatening infections. The usefulness of treating patients with CGD with IFN- γ was suggested by studies showing that this lymphokine can stimulate the respiratory burst of normal phagocytes. Results of studies by Ezekowitz and colleagues⁹⁸ and Sechler and coworkers²⁹⁶ showed that when macrophages from patients with CGD were treated with IFN- γ in vitro, a respiratory burst occurred, and superoxide anion was generated. Sechler and colleagues²⁹⁶ further demonstrated a partial correction in neutrophils and monocytes from patients with CGD after subcutaneous treatment with recombinant IFN- γ . These initial results suggested that when administered in vivo to patients with CGD, recombinant IFN- γ could partially correct the defective ability of phagocytes to kill bacteria. Ezekowitz and coworkers^{99,144} extended these findings in a double-blind, placebo-controlled trial. They showed that recombinant IFN- γ significantly decreased the relative risk for

development of serious infection in patients with CGD, but these studies failed to demonstrate an effect of IFN- γ on respiratory burst activity. This cytokine most likely affects the arginine-nitric oxide pathway in neutrophils and macrophages. Patients who received IFN- γ had a 70% reduction in the risk for development of serious infection compared with control subjects. Overall, IFN- γ decreases the risk for development of infection and the duration of hospitalization in patients with CGD. When IFN- γ is administered with prophylactic antibiotics, an additive effect occurs, resulting in a nearly 20% increase in the infection-free rate of patients with CGD compared with IFN- γ alone.⁹⁹ IFN- γ was licensed by the FDA in December 1990 for the treatment of patients with CGD. The authors of the collaborative studies recommended its use with the addition of prophylactic antibiotics for treatment of patients diagnosed with CGD.¹¹⁵

Clinical interest in the use of IFN- γ has focused on adjunctive immunotherapy in fungal infections. A randomized controlled trial evaluated the use of IFN- γ in 90 patients with HIV-associated cryptococcal meningitis, in which patients were assigned to one of three arms: (1) intravenous amphotericin B and oral flucytosine (standard therapy); (2) standard therapy plus two doses of IFN- γ ; or (3) standard therapy plus six doses of IFN- γ .¹⁶⁷ The rate of fungal clearance, defined as the mean rate of decrease in CSF cryptococcal CFU (early fungicidal activity [EFA]), was significantly more rapid in the IFN- γ treatment arms than in the standard therapy arm (difference in EFA was -0.15 logCFU/mL per day [$P = .02$] standard treatment vs. IFN- γ two doses; and -0.15 logCFU/mL per day [$P = .006$] standard treatment vs. IFN- γ six doses), although there was no significant difference in mortality between the groups at 2 weeks.

More recently, a randomized prospective phase IIb case series evaluated the use of recombinant IFN- γ in combination with anidulafungin (Eraxis) in 11 patients with invasive *Candida* and/or *Aspergillus* infections.⁸³ Eight patients were treated, and three were assigned to the control group and received placebo rather than IFN- γ . Two patients with invasive aspergillosis died, and one patient with *Candida* endocarditis developed intracerebral mycotic aneurysm. Peripheral blood mononuclear cells (PBMCs) were isolated before, during, and after treatment to assess the effect of IFN- γ on cytokine production. IFN- γ enhanced PBMC production of IL-17 and IL-22, cytokines that play a crucial role in fungal host defense, in response to *Candida* blastoconidia and hyphae in six of eight patients.⁸³ IFN- γ also increased the expression of human leukocyte antigen (HLA)-DR-positive monocytes in patients with a baseline starting at less than 50% (and thus considered immunosuppressed), suggesting partial restoration of immune function.⁸³

TOLL-LIKE RECEPTORS

Toll-like receptors (TLRs) are pathogen pattern-recognition receptors central to innate immune responses.¹⁶⁶ TLRs are a family of type 1 integral membrane glycoproteins that detect pathogens and initiate cytokine production by activation of nuclear factor κ B (NF- κ B). The ligands recognized by TLRs consist of a wide range of evolutionarily conserved motifs, such as LPS, single- and double-stranded RNA, and zymosan. Collectively, these motifs are called pathogen-associated molecular patterns (PAMPs). TLR recognition of PAMPs contributes to the immediate response and broad specificity of innate immune recognition toward bacterial, viral, fungal, and parasitic pathogens. Twelve TLRs have been described in mammals, with at least 10 known in humans.^{2,3,6}

The role of TLRs as immunomodulating agents is of contemporary interest. Amlie-Lefond and colleagues⁵ described the potential use of TLR agonists as protective agents against biothreat pathogens. TLR-1 to TLR-10 in humans act to augment the immune response. TLR agonists can bolster this response and potentially offer protection against specific infections or diseases. Stimulation of TLR-7 and TLR-8 has shown antiviral and antineoplastic properties in humans. A drug known to do this, imiquimod (Aldara), has been shown to be beneficial against human papillomavirus, molluscum contagiosum, genital warts, and basal cell carcinoma.^{5,71,318} Imiquimod has also been used to treat cutaneous squamous cell carcinoma *in situ*,²⁶⁴ although it is not FDA approved for this indication, and there is a case report of invasive

squamous cell carcinoma that developed following topical imiquimod treatment of carcinoma *in situ*.¹²³ Stimulation of TLR-2 by using pretreatment with PAM3CSK4, a TLR-2 agonist, has been studied in mice and was shown to increase bacterial clearance and decrease mortality in a mouse model of methicillin-resistant *Staphylococcus aureus* pneumonia.⁶⁶ TLR9 stimulation with CpG-oligodeoxynucleotide (CpG-ODN), which is found in bacterial and viral DNA, following introduction of a burn injury in a mouse model, with subsequent establishment of a secondary lung infection with *S. pneumoniae*, was shown to improve mouse survival significantly at 1 and 3 days when CpG-ODN was administered at 2 hours after traumatic injury.³²⁸ Lung washout samples analyzed at 1 day by time-of-flight mass cytometry showed increased expression of IL-17 in TCR $\gamma\delta$ T cells in the CpG-ODN-treated group (compared with the control group, which received saline). TCR $\gamma\delta$ -negative CpG-ODN-treated mice showed decreased pathogen clearance, a finding suggesting that TLR-9-stimulated IL-17-producing TCR $\gamma\delta$ T cells play a role in host defense against *S. pneumoniae* lung infection.

Immunomodulatory oligonucleotides stimulate TLRs and induce cytokine production. Immunomodulatory oligonucleotides offer potential clinical use for treatment of a number of inflammatory diseases, including severe acute respiratory syndrome, for which clinical trials are under way.⁵ Similar use of immunomodulatory oligonucleotides in patients with renal carcinomas and HIV infection also is under investigation. Evidence suggests that TLR-3 activation can enhance innate immune response and enhances production of IFN- α .¹⁸⁹ These features render TLR-3 agonists attractive agents in the treatment of HIV-related infections and infections in certain immunocompromised patients.

TLR expression in human neonates is currently being defined.²⁸⁷ TLR-2, TLR-4, and TLR-8 functions have been described in neonates. Researchers have speculated that deficiency of TLR activation may contribute to the neonate's increased susceptibility to infection.³²⁶ The results of TLR expression in neonates have varied. In general, similar expression of TLR-1 to TLR-4 occurs in neonates and adults. Low-birth-weight or premature infants, however, demonstrate significantly decreased expression of TLR-4.^{110,318} Most studies describe decreased cytokine production to TLR agonists in neonates compared with adults. In particular, TNF- α production is significantly lower in response to LPS stimulation of TLR-4 in neonates compared with adults, and it is speculated that this decreased stimulation may contribute to the neonate's increased susceptibility to *E. coli* and other gram-negative infections.^{58,192} Similarly, Levy and colleagues²⁰⁶ demonstrated that TLR-8 agonists are beneficial in activating costimulatory responses in neonatal antigen-presenting cells and suggested that this type of agent may be used adjutantly to enhance the neonatal immune response.

NEUTROPHILS AND COMPLEMENT

Recruitment of neutrophils from the bloodstream to extravascular sites of inflammation is a critical event in host defense against bacterial infection and in the repair of tissue damage. Under certain circumstances, accumulation of neutrophils may contribute to vascular and tissue injury. Thus, the regulatory mechanisms involved in neutrophil activation, recruitment, and subsequent degranulation are of potential clinical significance. Neutrophil adherence to and migration through capillary endothelium are critical early events in the acute inflammatory response. The adhesive interactions between leukocytes and endothelial cell surfaces are regulated by two novel families of glycoproteins: the integrins and the selectins. The β_2 integrins are membrane-bound glycoprotein receptors found on the surface of PMNs. The β_2 integrins CD11 and CD18 are required for adherence of PMNs to endothelial cell surfaces. The selectins also are membrane-bound glycoproteins that mediate neutrophil adhesion to endothelial cells. They include L-selectin, which is found on the surface of PMNs, and P-selectin and E-selectin, which are expressed on the surface of activated endothelial cells.^{28,57,309,335,354}

The interaction between the β_2 integrins and the selectins serves to regulate PMN responses during inflammation. In general, the selectins P and E on the activated endothelial cell surface and L-selectin on the PMN cell surface function to facilitate PMN rolling and tethering to activated capillary endothelium. Once this tethering has occurred and the PMN itself is activated, the β_2 integrin CD11/CD18 receptors on

the PMN form a tight adhesion with the endothelial cell surface that facilitates PMN attachment and polarization and leads to migration.^{28,57,309,354} Congenital β_2 integrin CD11/CD18 deficiency states have been described (leukocyte adhesion deficiency type I). These patients have profound PMN adhesion and motility defects and recurrent life-threatening infections, along with delayed separation of the umbilical cord and juvenile periodontitis.^{97,114} A second type, leukocyte adhesion deficiency type II, has been described as being caused by a deficiency of sialyl Lewis^x, the PMN ligand for E-selectin on endothelial cells.^{258,269} Researchers also have shown that the tethering of PMNs to P-selectin on activated endothelial cells is critical for PMN priming by PAF and that monoclonal antibodies to P-selectin can block this response.²¹⁴ Monoclonal antibodies to P-selectin have been used in animal models of ischemia and reperfusion injury and have been shown to reduce significantly the severe edema and endothelial cell injury observed after reperfusion.³⁴¹ Similarly, monoclonal antibodies to P-selectin have resulted in significant endothelial cell preservation in animal models of lung injury and cardiac ischemia.^{243,336} Monoclonal antibodies to E-selectin and L-selectin also are being tested in animal models.²²⁸ With the rapid advances occurring in identification of new molecules that influence endothelial cell–leukocyte interactions, we will gain greater understanding of the complexity of cellular communication during inflammation.

BACTERICIDAL/PERMEABILITY-INCREASING FACTOR AND DEFENSINS

In addition to their respiratory burst activity in antimicrobial defense, human neutrophils have been shown to contain a variety of granule-associated antibacterial proteins and peptides.²⁸⁰ These include bactericidal/permeability-increasing protein (BPI) and the defensin family of peptides. BPI is a 55-kDa receptor present in neutrophil granules, which contain two domains. One of the domains binds with LPS to increase membrane permeability and the lysis of gram-negative bacteria, whereas the other promotes the opsonization of gram-negative bacteria.¹⁵⁴ Neutrophil BPI functions best in inflamed tissues, where it acts in concert with defensins and the membrane attack complex of complement to cause cell lysis.

Meningococcemia is a severe gram-negative infection that occurs predominantly in infants and young adults. Mortality rates of meningococcemia range from 10% to 20%.^{9,40,141,337,343,353} Endotoxin levels may be profoundly elevated and correlate with the severity of the illness.³⁷ Recombinant BPI (rBPI) has been used as an adjunct to antimicrobial therapy in children with severe meningococcal sepsis²⁰⁴; 14 of 193 patients with severe meningococcal disease who received rBPI (2 mg/kg during 30 minutes) died, compared with 20 of 203 control infants, an insignificant difference. Among the surviving treated patients, however, a modest improvement was noted in long-term functional outcome, a finding suggesting a possible beneficial effect in decreasing complications associated with septic shock.^{121,204} Neonates have been shown to have reduced release and activity of BPI that may contribute to their enhanced susceptibility to gram-negative bacterial infections.²⁰⁵

The defensins are strongly cationic, single-chain peptides contained in neutrophil primary, or azurophilic, granules with molecular weights between 3 and 4.5 kDa. Defensins comprise 50% of the protein content of the neutrophil primary granules.^{116,350} These peptides possess broad antimicrobial activity against gram-positive and gram-negative bacteria, fungi, mycobacteria, and some viruses. The defensins create voltage-sensitive pores in microbial membranes, with resulting cell lysis. They are divided into α and β defensins. Humans have six human α defensins (HAD-1 to HAD-6) and two human β defensins (HBD-1 and HBD-2).

The α defensins, HAD-1 to HAD-6, are made by neutrophils and compose 30% to 50% of the primary granule content.¹⁴⁰ Defensins appear at the site of inflammation. They are present after neutrophil degranulation induced by LPS, IL-8, C5a, and other stimuli. They also are found on the epithelial surfaces of the bronchi and in bronchial lavage fluid of patients with various types of inflammatory lung disease. The antimicrobial activity of the defensins is inhibited by high salt content, which may be clinically important in the immune response of patients with cystic fibrosis.¹²⁵

The β defensins are produced by epithelial cells of the respiratory and gastrointestinal tracts.^{31,298} HBD-1 is expressed constitutively by epithelial cells in the bronchi and the intestine, whereas HBD-2 synthesis is upregulated by inflammatory stimuli, including LPS, TNF- α , bacterial infection, and injury. Thus, HBD-1 acts to kill organisms in the absence of inflammation, whereas HBD-2 acts primarily as part of the inflammatory process.

In inflammatory lung disease, such as chronic bronchitis and chronic obstructive lung disease, both α defensins HAD-1 to HAD-6 and β defensin HBD-2 may be increased significantly, perhaps contributing to airway inflammation.³⁵⁰ There are no reported clinical disorders of defensin production. Potential roles for the defensins as immunoregulatory-antimicrobial agents are being investigated.

Endotoxin and other proinflammatory mediators activate the complement system and the chemotactic properties of C5a, which recruits neutrophils to sites of infection. Interruption of this process at various levels may be possible with use of monoclonal antibody strategies that counteract the effects of the complement leading to septic shock. Although monoclonal antibodies directed at the specific components of the complement cascade have not been tested in human clinical trials, the use of monoclonal antibodies to inhibit C5a in primates challenged with *E. coli* improved the survival rate and reduced the incidence of adult respiratory distress syndrome.^{7,32}

PLATELET-ACTIVATING FACTOR

PAF is a potent phospholipid inflammatory mediator with many biologic effects. Its synthesis is regulated by phospholipase A₂, an enzyme associated with the arachidonic acid pathway. PAF has a very short half-life in vivo because of its rapid degradation by PAF acetylhydrolase. PAF is synthesized by many cell types, including macrophages, neutrophils, platelets, eosinophils, endothelial cells, and hepatocytes.³³⁸ Intravenous infusion of PAF into animals results in pulmonary hypertension, bronchoconstriction, neutropenia, thrombocytopenia, and ischemic bowel necrosis.^{24,64,136} Production of PAF is stimulated in numerous clinical disease states, including hypoxia and ischemia, and after administration of biologic agents such as LPS, GM-CSF, TNF- α , IL-1, bradykinin, and thrombin.^{102,190,231,232,271,284,342} Corticosteroids decrease levels of PAF by the induction of its natural inhibitor, PAF acetylhydrolase.¹²⁶ PAF has been shown to stimulate the production of many other mediators of inflammation, including TNF- α , complement breakdown products, oxygen radicals, catecholamines, prostaglandins, thromboxane, and the leukotrienes.^{104,160,190,283,322,353} It also activates endothelial cells and neutrophils and monocytes, thereby leading to their adherence and migration.²³⁰ Thus, PAF is a ubiquitous phospholipid mediator with many biologic effects and interactions within the inflammatory cascade.

The regulation of PAF has been studied in numerous potential clinical disease states, including sepsis and septic shock.¹⁵⁸ In clinical phase III trials in septic patients and patients in septic shock who received a PAF antagonist, a significant reduction in the mortality rate was noted.⁸⁵ The role of PAF, however, in the pathogenesis of NEC has received considerable attention.^{54,55} NEC is an often-fatal gastrointestinal disease that predominantly affects premature infants. Exogenous administration of PAF into rat mesenteric circulation causes ischemic bowel necrosis and disease similar to that seen in neonatal NEC.¹⁵⁹ Endotoxin-induced intestinal injury is associated with increased PAF levels, and the infusion of high doses of endotoxin into animals produces a similar pathologic model of NEC, which can be prevented by administration of dexamethasone, PAF acetylhydrolase, or PAF receptor antagonists.^{53,163} These animal studies suggest a link between PAF and its regulation and the development of NEC and implicate PAF as a potential endogenous inflammatory mediator in the pathogenesis of neonatal NEC.

Evidence in humans supports an association between PAF and human neonatal NEC. PAF levels are higher in infants with NEC compared with control subjects, and PAF acetylhydrolase activity is lower in infants with NEC.⁵⁶ PAF acetylhydrolase is suppressed with prematurity.⁵² Because enteral feedings are necessary for the development of NEC, PAF levels were measured in feeding premature infants. In these studies, feedings

alone increased circulating PAF levels but not PAF acetylhydrolase, and infants fed human breast milk had lower PAF levels and a lower incidence of NEC, a finding suggesting a protective effect of human milk through PAF regulation.²¹⁸ Human milk is known to have a number of factors protective against infectious disease, including PAF acetylhydrolase.^{48,124} Because PAF acetylhydrolase activity is present in human milk and absent in formulas, the suggestion has been made that the protective activity observed in human milk against the development of NEC may result from blocking of PAF-related inflammatory responses.⁴⁸ The modulation of the many interactions of PAF within the inflammatory cascade may have future clinical potential in regulating neonatal NEC and other inflammatory disease states.

NITRIC OXIDE

Nitric oxide is a membrane-permeable gas that functions in the regulation of vascular tone and in the inhibition of platelet aggregation and leukocyte adhesion. In addition, nitric oxide has been shown to have antitumor and antimicrobial activity. Under normal conditions, nitric oxide synthase induces endothelial cell production of nitric oxide. The signal transduction pathway for nitric oxide is linked to pathways involving vasodilation. Some evidence indicates that the L-arginine–nitric oxide pathway is activated in sepsis, in which the effects of nitric oxide on the vasculature are associated with the severe vascular failure observed during septic shock.^{68,69,179,241,248,249} Thus, inhibition of production of nitric oxide has been proposed as a novel approach for the treatment of the severe hypotension associated with septic shock.³³⁰

The increased production of nitric oxide observed during septic shock may have several harmful effects. Nitric oxide may be largely responsible for sepsis-induced hypotension. In vitro studies implicate nitric oxide in sepsis-induced myocardial depression, although nitric oxide synthase inhibitors have not been shown to prevent endotoxin-induced myocardial depression in vivo. Nitric oxide also has direct cytotoxic effects, and its overproduction in septic shock can lead to tissue injury and organ failure.^{68,105,177} In addition, in vitro experiments suggest that nitric oxide may enhance the release of proinflammatory cytokines during septic shock.^{96,248} Production of nitric oxide may, however, have some beneficial effects during septic shock. It is implicated in maintaining visceral and other microvasculature blood flow, both as a counterregulatory mechanism to the vasoconstrictive mediators released during sepsis and by its ability to block platelet adhesion, reducing potential microvasculature stasis and thrombosis.^{178,226} In addition, high levels of nitric oxide have antimicrobial activity and enhance LPS-induced production of cytokine,¹⁹¹ although whether these levels of nitric oxide reflect actual physiologic states has yet to be determined.

Because hypotension during sepsis is an important predictor of organ injury and death, use of nitric oxide synthase inhibitors may improve survival in severe septic shock by increasing mean arterial pressure. Nitric oxide synthase inhibitors have been shown to restore vascular responsiveness to catecholamines in animal models of endotoxin-induced septic shock.¹⁵⁵ In addition, nitric oxide synthase inhibition has been shown to normalize mean arterial pressure in anesthetized animals challenged with endotoxin or TNF- α without causing hypertension.¹⁷⁷ These considerations have led to the use of nitric oxide synthase inhibitors to treat hypotension in patients with sepsis and in patients receiving cytokine therapy for cancer.^{176,215} Although these agents can alter mean arterial pressure, beneficial effects on clinical outcomes, including survival, are only suggested in human clinical trials.²⁴⁸ Studies of endotoxin-challenged rats showed that partial nitric oxide synthase inhibition improved survival, whereas complete inhibition of nitric oxide production clearly was harmful, suggesting a beneficial effect with selective partial nitric oxide inhibition. Studies of nitric oxide inhibition that is more selective are being explored, and in the future such therapy may have clinical utility in the treatment of infectious disease states.

NANOTECHNOLOGY AND OTHER NOVEL TECHNIQUES

Nanomedicine is the application of nanoscale materials to medical treatment, diagnosis, and monitoring. There has been considerable

interest in the biomedical application of nanotechnology, particularly by the pharmaceutical industry for the development and improvement of drug delivery systems. The use of nanotechnology in the modification and improvement of the immune response to infectious diseases has also been an active area of investigation. Nanoparticle carrier platforms include biodegradable polymers, viruses and viral-like particles, liposomes, nanoemulsions, and gold microparticles, among others.¹⁸⁴ Nanoparticles can be loaded with immunomodulating compounds such as cytokines, immune-stimulating ligands, vaccine adjuvants, and DNA or RNA. For example, biodegradable nanoparticles with CpG-ODN (TLR-9 ligand) attached to the nanoparticle surface by biotinylation can be loaded with envelope protein antigen from the West Nile Virus, as an adjuvant to immunization, thus targeting intracellular TLR-9 activation and eliciting a robust Th1 polarized response in mice.⁸⁴ Poly(lactic-co-glycolic acid) (PGLA) polymer nanoparticles, an FDA-approved delivery platform, can be densely packed with small interfering RNA (siRNA) and delivered to the murine genital tract of mice infected with a lethal dose of intravaginal herpes simplex virus type 2, thereby improving survival dramatically from 9 days in untreated mice to >28 days in treated mice.³¹¹

Another advantage of nanoparticle delivery platforms is the ability specifically to target ligands to macrophages, for uptake of immunomodulatory agents and antibiotics. For example, tumor-associated macrophages (TAMs) that have adopted a protumor phenotype express high levels of mannose receptors, which can be targeted by ligand binding with mannosylated endosomal escape nanoparticles loaded with siRNA, thus allowing for manipulation of the NF- κ B pathway to induce antitumor characteristics in macrophages.²⁶⁰ Macrophage mannose receptors are also upregulated in parasitic infections, and mannose ligand-grafted chitosan nanoparticles have been used to deliver amphotericin B directly to macrophages infected with *Leishmania*, an obligate intracellular protozoan parasite that infects macrophages.¹⁴ This could potentially improve treatment and decrease the considerable toxic side effects associated with amphotericin treatment. Macrophage-specific nanodelivery platforms are also being investigated for use in the treatment of *Mycobacterium tuberculosis* infection, with the hope of developing alternative regimens for multidrug-resistant tuberculosis.³⁰⁶

Finally, adoptive cell transfer (ACT) technologies may also provide potential alternative treatment strategies for existing and emerging infectious diseases. ACT is already a promising therapy for cancer, in which tumor-infiltrating lymphocytes (TILs) from a sample of the patient's tumor are developed into multiple cell cultures with IL-2, assayed for tumor specific recognition, expanded to up to 10^{10} lymphocytes, and then reinfused into the patient following lymphodepletion (to remove T-regulatory cells and lymphocytes that compete with the transferred cells).²⁸⁵ Adoptive T-cell immunotherapy has shown great promise in the treatment of metastatic melanoma, with cancer regression as high as 50% in patients with melanoma.²⁸⁵ Adoptive T-cell transfer has also been proposed for the treatment of invasive fungal infections in immunocompromised patients, particularly patients undergoing hematopoietic stem cell transplantation (HSCT) for hematologic malignancies.²⁶³ Invasive *Aspergillus* infections have a very high rate of mortality in HSCT recipients. A clinical trial evaluated the adoptive transfer of donor PBMC-derived *Aspergillus*-specific T cells in 10 haploidentical HSCT recipients with *Aspergillus* pneumonia and galactomannan antigenemia.²⁶⁸ The negative control group consisted of 13 patients with invasive *Aspergillus* and/or galactomannan antigenemia who did not receive adoptive immunotherapy. Galactomannan antigenemia fell to normal levels within 6 weeks in the immunotherapy group but remained elevated in the control group for the duration of monitoring (15 weeks; $P < .002$ vs. control subjects). Nine of 10 patients in the treatment group cleared invasive *Aspergillus* in 7.8 ± 3.4 weeks, and 1 patient died ($P = .062$ vs. control subjects); six of 13 patients in the control group died. None of the patients who received immunotherapy developed graft versus host disease.

CONCLUSION

The initial attempts to augment immune function in the treatment of sepsis consisted of serum antibody therapy. The development of and

refinements in hybridoma and recombinant technologies have provided the means to generate highly specific monoclonal antibodies. Although monoclonal antibodies directed toward bacteria and their components currently are not used during a course of sepsis, the future of these antibodies may lie in their combination with antimicrobial pharmacologic agents to treat infections with certain pathogens. The advances in basic science and clinical research also have demonstrated that the cytokine family plays many crucial roles in the pathogenesis of septic shock. The interactions among the proinflammatory cytokines initiate the cascade of biologic events leading to the propagation and regulation of inflammation. Although the proinflammatory cytokines are effective in augmenting immune responses, their overexpression can lead to severe septic shock. The use of neutralizing monoclonal antibodies to endotoxin, anti-TNF- α antibodies, and soluble TNF- α and IL-1 receptors, as well as IL-1 receptor antagonists, in human clinical trials of septic shock, however, has shown limited therapeutic potential. The future clinical use of cytokine inhibition may include a combination of a number of both recombinant and pharmacologic agents temporally administered to regulate multiple proinflammatory cytokine-mediated steps in the development of septic shock. The hematopoietic growth factors have demonstrated considerable clinical effect, especially in individuals with distinct lymphopoietic disorders and in patients receiving immunosuppressive chemotherapy. IFN- α , IFN- β , and IFN- γ have received considerable attention as potential immunomodulators. IFN- α has shown broad clinical application as an antitumor agent, as well as an antiviral agent; IFN- β is being used with some success in patients with relapsing multiple sclerosis. The stimulatory effect of IFN- γ on human neutrophils is demonstrated in infants and children with specific neutrophil disorders and in neonatal sepsis. TLR agonists are emerging as attractive therapeutic agents in a number of infectious diseases. Investigations defining the actions of the integrins and the selectins, bactericidal/permeability-increasing factor and defensins, and PAF and nitric oxide may provide novel future clinical therapeutic approaches to attenuate acute inflammatory responses. Nanotechnology and adoptive cell transfer are technologies that will also provide novel therapeutic approaches and improve existing treatments for infectious diseases. As we learn more about the complexity of intracellular and extracellular interactions and the delicate balance of these molecules in regulating immune responses, we will be better able to implement their clinical use in regulating infectious disease states in infants and children.

Probiotics

Jonathan D. Crews

The resident microbes of the human microbiota contribute to the overall health of infants and children. Changes in the composition and diversity of intestinal microbial communities have been observed in various clinical conditions. Probiotics and prebiotics have been advanced as safe and effective methods to manipulate intestinal microbiota to prevent or treat disease in humans.

The study of the beneficial health effects of microorganisms began in 1908, when Elie Metchnikoff linked the longevity of Bulgarian peasants with the lactobacilli in the yogurt they consumed. In the early 1900s, Henry Tissier isolated *Bifidobacterium* from the stool of a healthy infant and claimed it could displace pathogenic bacteria in the gut.⁹⁵ In the 21st century, an enormous amount of basic and translational research has focused on the characterization and manipulation of the intestinal microbiota. In 2007, a major advance occurred with the formation of the Human Microbiome Project, sponsored by the National Institutes of Health, which aimed to determine the composition of the human microbiome, identify factors that affect its composition, and investigate the mechanisms by which the microbiome affects human health.⁷³

This chapter surveys probiotics and their application to the prevention and treatment of disease in newborns, infants, and children. Infectious diseases related to probiotic use also are reviewed.

DEFINITIONS

Probiotic Microorganisms

Probiotics is a general term for different species and strains of bacteria or yeast, usually commensal microorganisms of mammalian microbiota, which can promote health. The term is derived from Greek, meaning “for life.” The Food and Agriculture Organization of the United Nations and the World Health Organization define probiotics as “live microorganisms that, when administered in adequate amounts, confer a health benefit on the host.”^{67,103} Probiotic preparations may be administered as a single strain or mixture of multiple strains. They are available as stand-alone products—tablets, capsules, wafers, powder sachets, and liquid—and as ingredients in food and beverages. More than 100 probiotic products are available globally.⁹⁵

BOX 243.1 Microbial Species Used as Probiotics for Prevention and Treatment of Human Disease

Bacteria

Lactobacillus

L. acidophilus

L. bulgaricus

L. casei

L. delbrueckii

L. fermentum

L. helveticus

L. johnsonii

L. paracasei

L. plantarum

L. reuteri

L. rhamnosus

Bifidobacterium

B. bifidum

B. breve

B. infantis

B. lactis

B. longum

Streptococcus

S. salivarius

S. thermophilus

Enterococcus faecium (SF68 strain)

Escherichia coli (Nissle 1917 strain)

Clostridium butyricum

Bacillus

B. clausii

B. coagulans

B. subtilis

Yeast

Saccharomyces boulardii

The most common probiotic bacteria are strains of *Lactobacillus* and *Bifidobacterium* species. They are gram-positive commensals found in the human gastrointestinal tract. Additional probiotic bacteria include *Bacillus clausii*, *Clostridium butyricum*, *Escherichia coli* Nissle 1917, and *Streptococcus thermophilus*. *Saccharomyces boulardii*, a yeast organism, is a popular and well-studied probiotic (Box 243.1).

Lactobacillus species are gram-positive, nonmotile, non-spore forming bacilli. They produce lactic acid as an end product of carbohydrate fermentation and have been referred to as lactic acid bacteria. They grow best under microaerophilic conditions and form small to medium gray colonies that demonstrate α -hemolysis on blood agar. They are resident microorganisms in the human mouth, gastrointestinal tract, and vagina. The *Lactobacillus* genus has more than 170 species.⁵⁷ Although not all lactobacilli are acid tolerant and bile resistant, the strains used as probiotics have these features. Several *Lactobacillus* species are found in probiotic products: *L. acidophilus*, *L. bulgaricus*, *L. casei*, *L. paracasei*, *L. reuteri*, and *L. rhamnosus*.^{57,59}

Bifidobacterium species are gram-positive, nonmotile, non-spore forming, anaerobic organisms that are widely distributed among the gastrointestinal tracts of mammals, birds, and some insects. Bifidobacteria are one of the dominant bacterial members of the intestinal microbiota of infants.¹⁴⁹ *Bifidobacterium bifidum* was initially isolated from the stool of a healthy infant in 1906.⁹⁵ *Bifidobacterium longum* is one of the most abundant species in the human intestinal tract, and it is widely available as a probiotic.¹⁵¹ Other *Bifidobacterium* species used in probiotic products include *B. breve*, *B. infantis*, and *B. lactis*.⁵⁹

Saccharomyces boulardii was first identified from the surface of lychee and mangosteen fruit in 1920 by Henri Boulard.⁹⁵ It is considered a strain of *Saccharomyces cerevisiae*, a yeast used in baking and brewing. *S. boulardii* (i.e., *S. cerevisiae* var *boulardii*) has distinct metabolic and physiologic properties that make it better suited as a probiotic than *S. cerevisiae*.³⁴ *S. boulardii* grows optimally at 37°C, and is resistant to gastric acid and bile acids. Compared with bacterial probiotics, it has the benefit of being naturally resistant to antibiotics.³⁴

Prebiotics and Synbiotics

Prebiotics are nondigestible food ingredients that benefit the host by selectively stimulating the growth or activity of indigenous bacteria.^{53,54} The most common prebiotics are carbohydrates, which can be selectively fermented by species of resident intestinal microbiota. Examples include fructo-oligosaccharides (FOSs), inulin (i.e., FOS group), galacto-oligosaccharides, and lactulose.

Prebiotics increase stool colony counts of bifidobacteria and lactobacilli. They exert health effects through various mechanisms, including influencing the composition of the intestinal microbiota, improving intestinal barrier function, and direct modulation of the immune

system.^{118,131} For example, short-chain fatty acids (SCFAs) are important fermentation byproducts of prebiotics. They can interact with enterocytes and immune cells to strengthen the intestinal epithelium and modulate inflammation.

Human breast milk contains many oligosaccharides, which serve as natural prebiotics.⁴¹ Human milk oligosaccharides promote and stimulate the growth of beneficial, indigenous strains of bacteria, especially *Bifidobacterium* and *Bacteroides* species. Prebiotics are added to several commercial infant formulas.

A synbiotic product contains prebiotics and probiotics.¹⁴⁶ The combination of prebiotic dietary carbohydrates with probiotic bacteria can improve the survival and promote the activity of the probiotic strain, thereby enhancing the overall effect.

MECHANISM OF ACTION

The means through which probiotics influence health outcomes remains incompletely understood. Numerous mechanisms of action have been proposed based on basic and translational research. The current framework is that certain mechanisms are widespread and common to various probiotic genera, whereas others are species or strain specific. Although a single probiotic strain may produce health benefits through multiple mechanisms, no individual probiotic should be expected to employ all the proposed mechanisms.⁶⁷ Research articles have reviewed the evidence describing the mechanisms of action specific to *Lactobacillus* species, *Bifidobacterium* species, and *S. boulardii*.^{86,102,127}

Many clinical studies have demonstrated that probiotics can influence the composition of the intestinal microbiota.⁹⁴ The studies show that during intestinal dysbiosis (i.e., disruption or imbalance of microbiota), probiotics can promote the partial or complete restoration of intestinal microbiota. Reestablishment of a healthy intestinal microbiota is thought to be important for probiotics to exert their beneficial health effects. Swidsinski and colleagues studied 60 women receiving ciprofloxacin and metronidazole for bacterial vaginosis. Using fluorescence in situ hybridization, they found that *S. boulardii* CNCM I-1745, when administered concurrently or after the antibiotic regimen, reduced the antibiotic-associated changes of the fecal microbiota and improved the rate of microbial recovery.¹³⁶ In a clinical trial of 49 healthy adult patients, there was a lower rate of antibiotic-associated diarrhea and less pronounced shift in microbial communities when *S. boulardii* CNCM I-1745 was given with amoxicillin-clavulanate.⁷⁶

Probiotics appear to influence microbial composition through three mechanisms: direct and indirect antimicrobial effects, the ability to enhance the integrity and function of the intestinal mucosal barrier, and immune modulation.¹¹³ Several types of antimicrobial effects have been described for probiotics. They can exert colonization resistance, by which the colonization of enteric pathogens is hindered as the probiotic strain adheres to the intestinal epithelium or competes for necessary metabolites.¹³ Several probiotic strains produce antimicrobial products, including bacteriocins, hydrogen peroxide, and organic acids. Bifidobacteria can produce bacteriocins that possess antibacterial activity against *Clostridium difficile* and *E. coli*.⁹¹ Some probiotic strains can neutralize the bacterial toxins produced by enteropathogens. For example, *S. boulardii* can cleave *C. difficile* toxins and inactivate cholera toxin.¹⁰²

The intestinal barrier function is disrupted in several illnesses, including infectious diarrhea, irritable bowel syndrome, and inflammatory bowel disease. Maintenance of the integrity of the epithelial and mucosal layers of the colon is important in intestinal function. SCFAs are a metabolic byproduct of several probiotic strains and a major energy source for intestinal epithelial cells. They are instrumental in cell proliferation, cell differentiation, and mucus secretion.⁶¹ Probiotics can promote intestinal barrier integrity by enhancing the mucous layer and strengthening the tight junctions of the intestinal epithelial mucosa.¹²⁷

Animal models and observations in human studies support an association between intestinal microbial colonization and the development of the immune system. Probiotics appear to influence both local and systemic immune function through effects on the intestinal epithelium, gut-associated lymphoid tissue, and host immune cells.¹¹⁶ Local intestinal inflammation can be lessened through stabilization of intestinal barrier integrity, induction of antiinflammatory cytokines, and release

of secretory immunoglobulin A (IgA).^{127,133} Probiotics can enhance the production of protective cytokines, such as interleukin-10 and transforming growth factor- β , which inhibit epithelial cell apoptosis and enhance epithelial regeneration.¹¹³ Prebiotic oligosaccharides after fermentation into SCFAs have antiinflammatory effects on intestinal mucosa.⁶¹ Several strains of lactobacilli and bifidobacteria appear to influence the systemic immune system through effects on intestinal dendritic cells, regulatory T cells, IgA-producing B cells, and effector T and B cells.¹¹⁶

PROBIOTICS AND PREBIOTICS FOR PREVENTION AND TREATMENT OF CLINICAL CONDITIONS

Probiotic use is increasing. The National Health Interview Study found that 3.9 million adults in the United States consumed probiotic products in 2012, a fourfold increase from 2007.²⁸ Moreover, 294,000 US children 4 to 17 years of age used probiotics in the 30 days before the 2012 survey.¹⁸ Probiotic use is also increasing among inpatients. In a sample of 60 US hospitals, the number of hospitalizations during which probiotics were prescribed increased 2.9-fold between 2006 and 2012.¹⁶⁸

The rise in probiotic consumption has paralleled a surge in clinical research investigating their therapeutic and preventive potential. Numerous randomized, controlled trials (RCTs), albeit many with small sample sizes, have examined the effects of probiotics in various childhood disorders. Multiple meta-analyses have been derived pooled effect estimates from these trials. The meta-analyses have tended to evaluate probiotics as a therapeutic class, aggregating trials that employed different probiotic strains. This approach has been criticized due to growing evidence that probiotic strains have different mechanisms of action and health effects. In response, several investigators have performed meta-analyses of specific strains for various indications.^{26,48,140,152} In addition to differences in the probiotic strains, clinical trials vary in probiotic dose, timing, and duration; study populations; and methods of administration. These differences are certain to modify the outcome of probiotic trials.

The regulatory status of commercial probiotic products varies throughout the world.⁷⁷ In the United States, probiotic products are marketed as dietary supplements with generally recognized as safe (GRAS) status and do not require premarketing review by the Food and Drug Administration.^{68,159} In Europe, the European Food Safety Authority regulates probiotic products and their health claims. In most countries, there is limited regulatory oversight of the manufacturing process of probiotic products. Several issues related to the quality of probiotic products have been documented in many countries, including misidentification and mislabeling of probiotic strains, inaccurate labeling of viable organisms per dose, and contamination of products with potential pathogens.^{77,104}

Acute Infectious Diarrhea

Acute infectious diarrhea is a major cause of morbidity and mortality among children worldwide, particularly among children younger than 5 years. Multiple randomized trials have investigated whether probiotics can reduce diarrheal symptoms in children with infectious diarrhea. Most studies focus on young children with acute viral gastroenteritis, although some include children with bacterial or parasitic intestinal infections. *Lactobacillus rhamnosus* GG (LGG) and *S. boulardii* are the most frequently used strains in probiotic trials for infectious diarrhea. Other probiotic strains have been studied in randomized trials, including *L. reuteri* DSM 17938, *L. acidophilus* LB, *E. coli* Nissle 1917, *L. paracasei* strain ST11, and various multistrain combinations.^{43,65,66,128,141,152}

Several meta-analyses demonstrate that probiotics can shorten the duration of acute diarrhea in children.^{6,39,48,138,142} The 2010 Cochrane review, which included 63 RCTs, found that probiotics shortened diarrheal symptoms. The mean duration of diarrhea decreased by 24.8 hours (95% confidence interval [CI], 15.9–33.6 hours) and the risk of diarrhea lasting 4 or more days decreased by 59% (risk ratio [RR], 0.41; 95% CI, 0.32–0.53) in people receiving a probiotic.⁶

Lactobacillus rhamnosus GG significantly reduced the duration of diarrhea by 1 day (mean difference, 1.1 days; 95% CI, –1.7 to –0.4) when data from 11 clinical trials ($N = 2444$ participants) were examined.

LGG performed more effectively at a higher daily dose ($\geq 10^{10}$ colony-forming units [CFUs]) than a lower daily dose ($< 10^{10}$ CFUs).¹⁴² *Saccharomyces boulardii* also appears to alleviate symptoms of acute infectious diarrhea. A 2014 systematic review of 22 clinical trials found that *S. boulardii* reduced stool frequency on days 2 and 3 of illness and reduced the overall duration of diarrhea by 19.7 hours (95% CI, 13.3–26.1 hours).⁴⁸

Several organizations recommend probiotics for children with acute infectious diarrhea. The American Academy of Pediatrics (AAP) supports “the use of probiotics, specifically LGG, early in the course of acute infectious diarrhea.”¹⁴⁶ The European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) endorses the use of LGG (daily dose of $\geq 10^{10}$ CFUs) or *S. boulardii* (daily dose of 250–750 mg) as an adjunct to rehydration therapy for acute gastroenteritis.^{58,138}

Probiotics also have the potential to prevent acute diarrhea, particularly in children attending group childcare centers. RCTs performed in Mexico, Indonesia, Israel, and India found a modest benefit in the prevention of diarrheal illnesses in children attending childcare centers.^{3,60,135,163} Several probiotic organisms were studied, including *L. reuteri*, *L. casei*, and *B. lactis*. However, because rotavirus was an important cause of diarrheal disease in several of the trials, the results might not be generalizable to regions with widespread use of rotavirus vaccine.

Antibiotic-Associated Diarrhea

Approximately 10% to 20% of children receiving antibiotics experience diarrhea.^{74,80,147} Factors that increase the risk of antibiotic-associated diarrhea (AAD) in children include young age (< 2 years) and broad-spectrum antibiotics, including aminopenicillins (especially when administered with clavulanate), cephalosporins, and clindamycin.^{80,93} AAD can result from disruption of intestinal microbiota, overgrowth by enteric pathogens (especially *Clostridium difficile*), and metabolic alterations resulting in altered colonic digestion and absorption.⁹³

Probiotics can minimize the disruption of the intestinal microbiota caused by systemic antibiotics.^{76,94} Multiple RCTs found a modest benefit when probiotics were given concurrent with antibiotic therapy.^{8,52,79,122,157} *Saccharomyces boulardii* and LGG are the strains most extensively studied in AAD.^{139,140} Clinical trials evaluating multistrain products have had mixed results.^{30,52,144} Yogurt consumption has not been shown to prevent AAD in children or adults.¹¹⁴

Meta-analyses support the use of probiotics in the prevention of AAD.^{55,64,74} In a 2015 Cochrane review that included 22 RCTs ($N = 3898$ participants), the incidence of AAD among children in the probiotic group was lower than the control group (8% vs. 19%; RR, 0.46; 95% CI, 0.35–0.61). The number needed to prevent one case of diarrhea was 10.⁵⁵ The AAP and ESPGHAN endorse the use of LGG or *S. boulardii* to prevent AAD in children.^{137,146}

Clostridium difficile colonizes the intestinal tract after alteration of normal intestinal flora, most commonly after antibiotic therapy. Individuals with recurrent *C. difficile*-associated diarrhea (CDAD) have markedly diminished microbial diversity compared with healthy controls.²⁷ Meta-analyses indicate that probiotics may reduce the risk of CDAD by 65%.^{56,75} These studies, however, may not be generalizable to children because the included trials primarily studied adult patients. Nonetheless, preliminary studies of probiotics to prevent CDAD in children have yielded promising results.^{79,137,140}

Nosocomial Diarrhea

A 1994 clinical trial suggested that probiotics could prevent hospital-acquired diarrhea. In this randomized, placebo-controlled trial, hospitalized children 5 to 24 months of age who were given formula supplemented with *B. bifidum* and *S. thermophilus* had a lower rate of hospital-onset diarrhea than controls (7% vs. 31%; $P = .04$). Children receiving the supplemented formula also shed rotavirus at a lower rate.¹²³ A 2011 meta-analysis ($N = 3$ RCTs) found that administration of LGG for the duration of hospitalization decreased the incidence of symptomatic rotavirus gastroenteritis.¹⁴³ However, the included trials had methodologic limitations, and the results may not be generalizable to settings with a low incidence of health care-acquired rotavirus. In subsequent trials, neither *L. reuteri* DSM 17938 nor *B. lactis* BB-12 was effective in preventing hospital-onset diarrhea.^{69,153,161} Strict adherence to hand hygiene,

standard precautions, and appropriate isolation are the most important interventions to prevent hospital-acquired diarrhea. There is insufficient evidence to support the routine use of probiotics to prevent health care-associated diarrhea in children.

Persistent Diarrhea

Persistent diarrhea is a common condition in resource-limited countries among children 5 years of age or younger. A 2013 Cochrane review concluded that probiotics can reduce stool frequency and shorten the duration of persistent diarrhea, although the evidence remains limited.¹⁴ A randomized trial enrolling 235 children hospitalized in India with persistent diarrhea reported a shorter duration of diarrhea and shorter hospital stays for children taking LGG.¹²

Functional Gastrointestinal Disorders

Multiple clinical trials have evaluated the effect of probiotics on functional gastrointestinal disorders, including infantile colic, irritable bowel syndrome (IBS), functional abdominal pain disorders, and chronic constipation. Studies suggest probiotics are beneficial for infantile colic, IBS, and abdominal pain disorders, but they appear to have no effect on functional constipation.

Although the cause of infantile colic is unknown, it is considered a gastrointestinal disturbance. Infants with colic have decreased fecal microbial diversity compared with age-matched controls.³⁸ When *L. reuteri* DSM 17938 is administered to infants with colic, particularly breastfed infants, a positive therapeutic effect has been observed. A meta-analysis ($N = 6$ RCTs) found that infants in the *L. reuteri* group ($n = 213$), when compared with the placebo group ($n = 210$), had decreased crying time at 2 weeks and 3 weeks but not at 4 weeks.¹⁶⁷ The effect may be limited to breastfed infants because the only unsuccessful trial in the meta-analysis included formula-fed infants.¹³⁴ *Lactobacillus reuteri* DSM 17938 may also decrease the incidence of other functional gastrointestinal disorders in young infants.⁷¹

Probiotics can reduce abdominal pain and discomfort in children with IBS and functional abdominal pain disorders.^{78,108} In 2017, a Cochrane review ($N = 13$ RCTs) reported that children with recurrent abdominal pain or IBS experienced a reduction in pain when treated with a probiotic.¹⁰⁸ However, the studies were of low to moderate quality due to heterogeneity, incomplete outcome data, and small sample size. The probiotic strains evaluated in the included studies were LGG, *L. reuteri*, or multistrain products. *S. cerevisiae* CNCM I-3856 and *Bifidobacterium* species have also been studied in adults with IBS.^{26,169} Further research is needed to characterize the optimal probiotic regimen (i.e., strain, dose, and timing) for children with IBS or functional abdominal pain.

Probiotics do not improve functional constipation.⁷⁸ Current recommendations from the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) and ESPGHAN do not support their use for the treatment of childhood constipation.¹⁴⁵

Helicobacter Pylori Infection

RCTs demonstrate that probiotics, when administered with triple therapy to children with *Helicobacter pylori*, can improve the eradication rate and decrease therapy-related side effects, particularly diarrhea.⁸⁵ An increase in adherence to treatment may explain the increased cure rate.¹⁷ These trials are encouraging, but the optimal probiotic strain has not been identified. Further evidence is needed in children before probiotics are routinely used with standard *H. pylori* treatment.¹⁴⁶

Inflammatory Bowel Disease

Pediatric patients often receive probiotics as adjunctive treatment for inflammatory bowel disease (IBD).¹⁶⁵ However, there are few large, well-designed clinical trials on their use with ulcerative colitis (UC) or Crohn disease (CD). A small study of 29 children with UC found that those receiving a commercial probiotic product containing eight strains achieved and maintained remission at a higher rate than those receiving placebo.⁹⁷ However, systematic reviews have not found a consistent benefit for probiotics in UC in induction or maintenance of disease remission.^{89,107} There has been less clinical research on the use of probiotics in CD. Cochrane reviews have concluded there is no evidence to support their use in CD.^{22,120}

Liver Disease

Given evidence of the interplay between the intestinal microbiota and the liver (i.e., gut-liver axis), early efforts are underway to investigate whether probiotics are effective in the prevention and treatment of pediatric liver disease.¹⁰¹ Increased intestinal permeability and alterations in intestinal microbiota have been observed among children with nonalcoholic fatty liver disease (NAFLD), the most common chronic liver disease in children living in industrialized countries.¹⁰⁹ Three small clinical trials suggest that probiotics, when administered to obese children with NAFLD, modestly improve levels of alanine aminotransferase and decrease hepatic steatosis regardless of body mass index.^{5,47,154}

Individuals with hepatic encephalopathy may benefit from probiotics. Clinical trials enrolling adult patients suggest that probiotics can hasten recovery and decrease plasma ammonia concentrations but do not affect overall mortality rates.³⁵

Allergic and Atopic Diseases

Disturbances in the composition of the gut microbiota may play a role in the pathophysiology of allergic diseases by modifying local intestinal immunity and altering systemic immune programming. The hygiene hypothesis suggests that reduction in general microbial exposure during early childhood may increase susceptibility to allergic disease by reshaping the development of the immune system. Probiotics have been advanced as a method to prevent inappropriate immune development through maintenance of healthy intestinal microbiota.

Several clinical trials examined whether probiotic use during pregnancy or infancy, or both, influence the risk of developing allergic diseases. Overall, the research suggests that probiotics have a modest effect on the prevention of atopic dermatitis in at-risk infants (i.e., those with an immediate family member with allergic disease).^{32,50,51,115,171} There is very limited evidence that probiotics have an impact on the development of allergic rhinitis, food allergies, or asthma/wheezing.^{32,44,171}

In a 2007 study, pregnant women carrying children at high risk for atopic disease were randomized to receive a multistrain probiotic preparation (i.e., *L. rhamnosus* GG, *L. rhamnosus* DSM 7061, *B. breve* Bb99, and *Propionibacterium freudenreichii*) or placebo for 2 to 4 weeks before pregnancy, with their children receiving the same product for 6 months. By 2 years of age, children receiving probiotic therapy had a lower rate of atopic dermatitis (odds ratio [OR], 0.74; 95% CI, 0.55–0.98) and immunoglobulin E (IgE) –associated atopic dermatitis (OR = 0.66; 95% CI, 0.46–0.95).⁸¹ A 2012 meta-analysis ($N = 13$ RCTs) reported a 25% reduction in the incidence of atopic dermatitis and IgE-associated atopic dermatitis. This effect, however, was documented only in the first 2 years of life and appeared to disappear by 5 years of age. There was significant heterogeneity among the included trials.¹¹⁵

Prebiotics may reduce the risk of developing allergic disease. Although there are fewer trials, the results are promising and suggest that giving prebiotics to infants may reduce the incidence of atopic dermatitis.¹¹¹

The AAP and the European Academy of Allergy and Clinical Immunology do not endorse probiotics or prebiotics to prevent allergic disease due to limited scientific evidence.^{106,146} In contrast, the World Allergy Organization (WAO) recommends prebiotics and probiotics to prevent atopic dermatitis. For infants who are not exclusively breastfed, the WAO recommends probiotic supplementation.³³ They also support probiotics for pregnant women at high risk for having an allergic child, women breastfeeding infants at high risk for allergic disease, and infants at high risk for allergic disease. They acknowledge that the recommendations are based on low-quality evidence, but the WAO concludes that the potential benefits outweigh any safety concerns. The WAO does not specify a particular prebiotic product or a probiotic strain, dose, or duration.⁴⁹

There is less research on the role of probiotics in the treatment of allergic diseases. A few preliminary studies found that probiotics may reduce symptoms of allergic rhinitis or atopic dermatitis. However, further studies are needed before definitive conclusions can be reached.^{20,170}

Human Immunodeficiency Virus Infection

Individuals with human immunodeficiency virus (HIV) infection have a fecal microbiota profile distinct from healthy controls.¹⁶⁴ Preliminary

studies suggest probiotics may improve the well-being of HIV-infected patients. Several studies have documented a modest increase in CD4 counts during probiotic use.^{24,100} However, the effect of probiotics on HIV-associated diarrhea, including antiretroviral-associated diarrhea, has been mixed.²⁴ Overall, the evidence remains inconclusive on whether probiotics should be routinely administered to HIV-infected people.

Upper and Lower Respiratory Tract Infections

Growing evidence supports the notion that alterations in the intestinal microbiota can modulate the function of the innate immune system.¹⁴⁸ This finding has prompted investigation of the impact of probiotics on the prevention of respiratory infections.⁴⁶ In an RCT enrolling 638 childcare attendees 3 to 6 years of age, use of a fermented dairy drink containing *L. casei* mildly decreased the incidence of upper respiratory infections (URIs) compared with placebo (incidence rate ratio = 0.82; 95% CI, 0.68–0.99).⁹⁶ A 2015 Cochrane review ($N = 12$ RCTs) involving infants, children, and adults ($N = 3720$) found that probiotics appeared to prevent acute URIs, as measured by the number of people experiencing one or more episodes (OR = 0.53; 95% CI, 0.37–0.76) or three or more episodes (OR = 0.53; 95% CI, 0.36–0.80). There was also a lower rate of antibiotic prescriptions and a lower incidence of URI-related school absences in the probiotic group. However, when the URI rate (i.e., URI events per person-year) was measured, there was no difference between the probiotic and placebo groups. Several trials included in the analysis were determined to be of low or very low quality.⁶²

Necrotizing Enterocolitis and Neonatal Sepsis

Meta-analyses have consistently found probiotics to reduce the incidence of necrotizing enterocolitis (NEC) among preterm neonates.^{4,16,110} For example, a 2014 meta-analysis ($N = 24$ RCTs), which included 5529 preterm (<37 weeks' gestational age) or low-birth-weight (<2500 g) infants, found that probiotics decreased the incidence of NEC stage 2 or higher (RR, 0.43; 95% CI, 0.33–0.56) and mortality (RR, 0.65; 95% CI, 0.52–0.81).⁴ Similar results were observed for very-low-birth-weight infants (<1500 g); however, the number of extremely-low-birth-weight (ELBW) infants (<1000 g) was too small to perform a meaningful analysis.

Several publications suggest that probiotics may decrease the incidence of late-onset sepsis, improve feeding tolerance, and shorten hospitalization.^{2,117} Many different probiotic strains have been studied in neonates, including *L. acidophilus*, *L. reuteri*, *L. rhamnosus*, *B. bifidum*, *B. breve*, *B. infantis*, *S. boulardii*, and multistrain products.^{9,63,72,87,150} Although many of these probiotic strains proved useful, there is evidence that not all probiotic strains are beneficial for preterm infants.¹ For example, a large and rigorous clinical trial ($N = 1310$) found that *Bifidobacterium breve* BBG-001 had no impact on the incidence of NEC, late-onset sepsis, or mortality for preterm infants.³¹

Neonatal centers throughout the United States and Europe routinely administer probiotics to preterm infants.¹⁶⁰ Some experts, however, have concerns about the increasing use of probiotics in preterm neonates. They cite issues with the quality of trials included in meta-analyses, the heterogeneity among published studies, the lack of an established probiotic regimen (i.e., strain, dose, and timing), and the absence of quality control regulations to ensure consistency and safety of probiotic products.^{98,99} The AAP does not endorse the routine use of probiotics in preterm infants, but it does acknowledge there is “some evidence” to support their use to prevent NEC in infants weighing more than 1000 g.¹⁴⁶

SAFETY OF PROBIOTICS AND PREBIOTICS IN INFANTS AND CHILDREN

Probiotics and prebiotics appear to be safe for infants and children. An analysis of 74 clinical trials, containing 7798 children who received a probiotic, did not identify any major safety concerns. No serious adverse events attributable to probiotics were reported, nor were there any infections from the administered probiotics. However, the documentation and reporting of adverse events was poor among many of the included studies.¹⁵⁶ Nonetheless, probiotics, although not without risk, appear to be safe for healthy infants and children. For high-risk or special

patient groups, the safety of administering products containing live microorganisms requires careful consideration. The risks of probiotic use must be carefully balanced with the potential benefits.

Severe infections, including sepsis and meningitis, caused by probiotic microorganisms can occur in infants and children. Although uncommon, these events can be serious or fatal. Populations at risk include immunocompromised patients, preterm and low-birth-weight neonates, children with intestinal disorders, and patients with indwelling venous catheters.⁴²

There is concern that probiotics may transfer antibiotic-resistance genes to pathogenic bacteria. Although there is no evidence that this has occurred, there is evidence to support the principle. Many probiotic strains possess genes that confer resistance to one or more antibacterial agents.^{70,158} Xiao and colleagues, during a study evaluating the antibiotic susceptibility of *Bifidobacterium* species in commercial probiotic products in Japan, found *B. lactis* strains that harbored a plasmid-mediated *tet(W)* gene that conferred tetracycline resistance.¹⁶⁶ Mater and associates described the in vivo transfer of vancomycin resistance (i.e., *vanA* cluster) from a clinical *Enterococcus faecium* strain to a commercial strain of *L. acidophilus* during digestive passage in mice.⁹² Lund and Edlund demonstrated the potential for a probiotic *E. faecium* strain (i.e., SF68) to receive the *vanA* gene cluster.⁸⁸ Collectively, these studies highlight the possibility of gene transfer between probiotic organisms and other microbes.

The purity of probiotic supplements, given the lack of regulatory oversight of the manufacturing process, is an important concern. Commercial probiotic products contaminated with cow's milk allergens have caused severe allergic reactions in children.^{83, 90} In October 2014, a preterm neonate developed gastrointestinal mucormycosis related to contamination of a probiotic product with *Rhizopus oryzae*.¹⁵⁵

INFECTIOUS DISEASES RELATED TO PROBIOTIC USE

As living microorganisms, probiotics have the potential to cause infectious diseases. Bloodstream infections are the most commonly reported infection. Serious, invasive infections have included meningitis, pneumonia, intraabdominal abscesses, and orthopedic hardware infections.

Bacteremia from *Lactobacillus* and *Bifidobacterium* species and fungemia from *Saccharomyces* species have been documented in infants and children.^{10,36,45,129} However, the risk of bloodstream infections during probiotic use is very low. From 1995 to 2000, lactobacilli represented 0.2% of all positive blood cultures in Finland. There was no temporal change in the incidence of *Lactobacillus* bacteremia despite a substantial increase in the use of LGG during the study period.¹²⁶

Bloodstream infections from probiotic organisms seem to be rare in immunocompromised patients. A large cancer center reported a low incidence of bloodstream infections due to *Lactobacillus* and *Saccharomyces* among hematopoietic stem cell transplant recipients.²⁹

Invasive infections from *Lactobacillus* species have been described in neonates, children, and adults.^{23,36,37,82} Bacteremia from *Lactobacillus* is the most commonly reported infection related to probiotic use. Not every infection from *Lactobacillus*, however, is attributable to probiotic use. Studies have demonstrated that lactobacilli isolated from human infections can be unrelated to the lactobacilli organisms in probiotic products.^{7,112} Studies demonstrate that lactobacilli, as resident intestinal microbes, can originate from the host's microbiota. Infections from *Lactobacillus* have included neonatal sepsis, endocarditis, pneumonia, meningitis, liver abscess, intraabdominal abscess, and prosthetic joint infection.^{19,21,23,40,119,124,130,132} Risk factors include immunocompromised status, indwelling central venous catheters, probiotic use, and recent surgical intervention.

Lactobacillus infections in children have been successfully treated with penicillin, ampicillin, clindamycin, or combination therapy (i.e., β -lactam antibiotic plus aminoglycoside).^{36,82} Lactobacilli tend to be resistant to vancomycin and fluoroquinolones; have variable susceptibility to penicillin, cephalosporins, and aminoglycosides; and have low minimum inhibitory concentrations (MICs) for piperacillin-tazobactam, clindamycin, and carbapenems.^{84,125}

Bacteremia from *Bifidobacterium* has been documented among premature neonates receiving probiotics to prevent NEC. These rare cases have occurred in patients with abdominal pathology, including omphalocele, intestinal necrosis, and NEC.^{15,45,162} A case of *Bifidobacterium breve* bacteremia was also reported in a child with acute lymphoblastic leukemia.¹¹

Infections from *S. cerevisiae* and *S. boulardii* have been described in children and adults.^{10,105,121} Fungemia is the most common clinical syndrome described, although endocarditis, pneumonia, liver abscess, peritonitis, and urinary tract infections have occurred.¹⁰⁵ Most fungemia cases have occurred in critically ill patients in intensive care units (ICUs). Risk factors include receipt of *S. boulardii* probiotic products, presence of indwelling central venous catheter, and receipt of broad-spectrum antibiotics.^{10,105} *Saccharomyces* species can enter the bloodstream by intestinal translocation or external contamination of venous catheters. For example, an outbreak of *S. boulardii* fungemia included ICU patients who were not consuming probiotic supplements but were roommates of patients receiving lyophilized probiotic products.²⁵

The management of *Saccharomyces* fungemia includes removal of indwelling vascular lines and antifungal therapy. Amphotericin B is the most frequently used agent, and clinical isolates of *Saccharomyces* are consistently susceptible to it. Fluconazole has also been used successfully to treat fungemia, although resistance has occasionally been reported.¹⁰⁵

Health care–associated (nosocomial) infections (HCAs) are infections that occur as a consequence of health care. Many are associated with the use of modern invasive devices and procedures that breach normal host defenses and allow microbial invasion. Other infections result from exposure to pathogens in the health care environment that are transmitted from colonized or infected people or from contaminated objects and surfaces, water, or air; they may occur in those who have compromised immune systems or are particularly susceptible to infection, such as preterm infants. HCAs also may occur in people delivering health care (i.e., occupationally acquired infections in health care providers).

HISTORICAL BACKGROUND

The history of HCAs and their control is tightly linked to developments in institutional medical care.⁶⁵² Although not broadly recognized, efforts to study and prevent infection among hospitalized children have contributed significantly to the development of infection control and prevention efforts in general.

Semmelweis' classic studies of puerperal fever in the Vienna Lying-In Hospital in the mid-1800s provided insights into the cause and prevention of perinatal infections in neonates, not just their afflicted mothers.⁶⁵³ Children also suffered greatly from the epidemics of contagious diseases that spread through hospitals during the 18th and 19th centuries.²³⁴ This problem led to the opening of wards and entire hospitals designated for the treatment of patients with infectious diseases in the early 20th century.⁶⁵² By the mid-20th century, a number of interventions had been developed to minimize the spread of contagious diseases in hospitals, including the use of quarantine areas for new admissions, confinement of each child in an individual cubicle, creation of cohorts for patients admitted during community epidemics, use of masks by people caring for patients, exclusion of visitors, strict control of the health of nurses and physicians caring for the patients, and implementation of exhaust fans to prevent airborne transmission of measles and varicella.^{67,86,293,417,437}

Outbreaks of *Staphylococcus aureus* infection in hospitalized infants had been documented in the late 1800s and early 1900s,^{101,357} but the pandemic of *S. aureus* infections that plagued hospitals in the 1950s and 1960s drew special attention to the impact of infections caused by this organism. Outbreaks of staphylococcal disease were particularly devastating in neonatal nurseries, where epidemics caused by specific phage types caused substantial morbidity and mortality.⁶⁴⁰ The seriousness of the hospital-acquired staphylococcal infection problem spawned more comprehensive efforts to document the impact and consequences of hospital-acquired infections^{609–611} and served as the impetus to develop organized infection control programs, particularly in Great Britain (with its tradition of infection control sisters) and North America.

In 1970, a hospital-acquired infection surveillance and control program was established at Children's Hospital in Boston, and data were reported to the nascent National Nosocomial Infections Study at the Centers for Disease Control and Prevention (CDC).²⁴⁰ The study emphasized the association of hospital-acquired infections with exposure to invasive devices and procedures. Additional epidemiologic studies of infections in pediatric patients cared for in intensive care units (ICUs) during the 1970s and early 1980s strengthened the association between the use of invasive devices and procedures and hospital-acquired infections.^{263,299,310,454}

Advances in viral diagnostics in the 1970s led to greater appreciation of the importance of viruses as a significant cause of hospital-acquired infections, particularly in pediatric patients.^{737,765} Spread of respiratory and gastrointestinal viruses, especially respiratory syncytial virus (RSV)

and rotavirus, was documented as a severe problem on pediatric wards.^{189,283,486,616,765}

In the past 40 years, problematic pathogens continue to emerge and reemerge as causes of HCAs. Gram-positive bacteria, including coagulase-negative staphylococci, *S. aureus*, enterococci, and streptococci, have remained significant pathogens in hospitalized patients.^{224,271,335,688} Antimicrobial-resistant bacteria, such as methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant enterococci (VRE), and gram-negative bacilli resistant to third-generation cephalosporins, aminoglycosides, carbapenems, and quinolones are especially problematic.^{305,330,363,441,442,585} Although MRSA has received the most attention in the media, gram-negative pathogens, such as carbapenemase-producing Enterobacteriaceae, *Burkholderia*, *Stenotrophomonas*, and *Acinetobacter* are even more problematic because they are resistant to most (or all) available antibiotics, and the pipeline of new active agents is very limited.⁷⁵

Overuse of antibiotics is in part responsible for the continued increase in *Clostridium difficile* infections,¹²⁰ but the clonal spread of more virulent strains of *C. difficile* (e.g., NAP-1) has been a major problem for adults and children.^{411,435,476,731} Many studies have documented an increase in *C. difficile* infection among hospitalized children over the past decade.^{169,360,528,631,632,786}

As increasing numbers of severely ill and immunosuppressed children are cared for in hospitals, the incidence of fungal infection has increased dramatically, especially infection caused by *Candida* and *Aspergillus*.^{1,224,229,475} Health care–associated acquisition of respiratory viruses, such as RSV, parainfluenza virus, and adenovirus, can cause severe and sometimes lethal pneumonia in these patients. HCAs also can be caused by bloodborne pathogens, such as the human immunodeficiency virus (HIV), hepatitis B, hepatitis C, and parvovirus B19 among patients and health care workers.^{113,119,109,277,547,691,727}

International outbreaks of infection, including severe acute respiratory syndrome (SARS), Middle East respiratory syndrome (MERS), pandemic influenza, and Ebola virus disease,^{45,529,598,721} have been fueled by transmission in health care facilities. Health care workers have borne a substantial burden of disease from these infections.

For the past 2 decades, HCAs have been viewed through the lens of efforts to improve the quality and safety of health care.^{329,370} Most states require public reporting of institutional rates of HCAs, and the Center for Medicare and Medicaid Services (CMS) requires facilities providing care for Medicare and Medicaid patients to report rates of HCAs, with comparative data available for public viewing on the CMS's Hospital Compare website (www.hospitalcompare.hhs.gov). These infections are broadly recognized as important contributors to the preventable harms that affect patients as a consequence of health care, and a consortium of leading professional societies and governmental groups has issued a call to action for their elimination.¹⁰⁴ Initiatives to reduce HCAs have been among the most prominent of the patient safety success stories,^{117,577,576} and many multicenter collaborative networks are actively working on prevention of HCAs in children.^{64,314,444,490,647}

The U.S. Department of Health and Human Services is engaged in these efforts through its National Action Plan to Prevent Health Care–Associated Infections: Roadmap to Elimination (<https://health.gov/hcq/prevent-hai-action-plan.asp>) and the Partnership for Patients (<https://partnershipforpatients.cms.gov/>), a program that focuses on reducing preventable harms, including HCAs, and readmissions. President Obama also took a leadership role in addressing the worldwide crisis in antimicrobial resistance through the President's Council of Advisors on Science and Technology Report to the President on Combating Antimicrobial Resistance (https://obamawhitehouse.archives.gov/sites/default/files/microsites/ostp/PCAST/pcast_carb_report_sept2014.pdf)

and the White House's subsequent National Action Plan for Combating Antibiotic-Resistant Bacteria (https://obamawhitehouse.archives.gov/sites/default/files/docs/national_action_plan_for_combating_antibiotic-resistant_bacteria.pdf).

The remaining sections of this chapter expand on these themes by describing HCAs due to spread of communicable infections in health care facilities, infections related to invasive devices and procedures, infections caused by special pathogens, infections occurring in special populations, the components of programs to prevent these infections, and programs to optimize antimicrobial stewardship.

SPREAD OF COMMUNICABLE INFECTIONS IN HEALTH CARE FACILITIES

General Principles

HCAs that occur as a result of spread of communicable infections common in the community are a major concern for all facilities providing health care to children. Several principles regarding the epidemiology of these infections, modified from those initially published by Hall,²⁸⁰ are summarized here. First, their appearance and spread on the wards parallels closely the disease activity in the community. Second, exposure to these pathogens usually results in infection in any host who lacks specific immunity; consequently, a susceptible child is at risk regardless of the nature or severity of his or her underlying disease or medical treatment. Third, these infections are often more severe in patients who have underlying diseases (e.g., prematurity, pulmonary or cardiac disease) or who are immunocompromised. Fourth, children hospitalized as a result of the community-acquired infections comprise the most important reservoir for microorganisms causing these infections, but mildly symptomatic or asymptotically colonized adult caregivers and visitors may be important reservoirs for some agents (e.g., RSV, pertussis). Fifth, prevention depends primarily on the timely implementation of and adherence to isolation precautions designed to interrupt the modes of transmission of the microorganisms involved. In some situations, other interventions are indicated, such as chemoprophylaxis for infants exposed to pertussis and immune globulin for high-risk individuals exposed to measles. Sixth, unless postdischarge surveillance is performed, the frequency of these infections can be underestimated because of short hospital stays and some infections (e.g., *C. difficile* infection) may be incubating at the time of discharge and manifest only after the child returns home.

Modes of Transmission

Airborne transmission involves spread of microorganisms by droplet nuclei, which are small particles (<5 µm) generated by the desiccation of larger respiratory droplets, especially those expelled by coughing. Because they are extremely light, droplet nuclei can travel very long distances on air currents. The small droplet nuclei can remain suspended in inhaled air, evading the mechanical host defenses of the upper respiratory tract, to reach the distal airways and alveoli.⁵⁰² Diseases spread by airborne transmission of respiratory droplet nuclei include measles, tuberculosis, smallpox, and under certain circumstances, influenza and varicella.^{159,404,504,592,736}

Droplet transmission involves transfer of microorganisms by large respiratory droplets, such as those generated by coughing or sneezing, which typically travel short distances in the air before settling. Important pathogens spread by this route include *Bordetella pertussis*, *Neisseria meningitidis*, and group A streptococci.

Contact transmission is the principal mode of transmission for most HCAs. Direct contact transmission involves physical contact between a person harboring the microorganism and a susceptible host, such as a caregiver with a herpetic whitlow who transmits the virus to a neonate. Indirect contact transmission involves transfer of microorganisms by an intermediary person, object, or surface. The hands of caregivers are a common source of indirect contact transmission,⁷⁶ but fomites and contaminated environmental surfaces are also important for certain pathogens (e.g., RSV, *C. difficile*, MRSA, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, norovirus).^{544,755}

Endogenous infection or autoinfection is caused by a patient's own colonizing flora, usually as a consequence of host defenses that are

compromised by severe underlying disease, immunosuppressive therapy, or invasive devices and procedures. Endogenous infections may be caused by microorganisms that are a part of the normal microbiome (e.g., coagulase-negative *Staphylococcus*) or that are acquired from exposure to the health care environment, usually by indirect contact transmission, and become persistent colonizers (e.g., VRE). These infections can be considered as a special case of contact transmission.

Common vehicle (i.e., common source) transmission involves the widespread dissemination of a microorganism to many people by a contaminated item or substance. Examples include recent outbreaks of hepatitis B and C due to blood contamination of reused items^{113,277} and outbreaks caused by nonenteric gram-negative bacilli, such as *P. aeruginosa*, that thrive in medications, solutions, or wet equipment and are relatively resistant to preservatives, antiseptics, and disinfectants.

Vector transmission of microorganisms on (i.e., extrinsic) or within (i.e., intrinsic) insects is possible, but it is rare in hospitals.^{46,123,225}

Some infections may be spread by more than one mode of transmission. For example, varicella zoster virus may be spread by airborne and contact transmission.

Standard and Transmission-Based Precautions

The CDC's Healthcare Infection Control Practices Advisory Committee's (HICPAC) guideline for isolation precautions describes strategies to prevent spread of communicable infections in health care facilities.⁶⁶⁸ These strategies involve the use of *standard precautions*, which should be used for all hospitalized patients at all times, and *transmission-based precautions*, which are used for patients with suspected or confirmed infections that may be transmissible to other patients or health care workers. Transmission-based precautions include *airborne precautions*, *droplet precautions*, and *contact precautions*, each of which is designed to interrupt one of the described modes of transmission. The key components of standard precautions and transmission-based precautions are outlined in Boxes 244.1 and 244.2 and are described in more detail later in this chapter (see [Infection Prevention and Control Programs in Health Care Facilities](#)).

Respiratory Viruses

RSV is the most common health care–associated respiratory virus infection, especially among children younger than 2 years of age, because RSV infection accounts for a substantial number of hospital admissions of young children during epidemic periods.^{77,282,332,396,660,743} In the absence of effective infection prevention and control programs, attack rates can be high because immunity after infection is short lived, inoculation of virus into the nose or eyes reliably leads to infection, infected children excrete high titers of virus in their copious secretions, and RSV survives for long periods in the environment.^{284,286,281,282} Risk factors for health care–associated RSV infection are prematurity, heart and lung disease, immunocompromising conditions, and duration of hospitalization.^{287–289,396,448,675,743}

The transmission of RSV can be markedly reduced by scrupulous attention to hand hygiene and the use of gloves and gowns when touching patients or their immediate inanimate environment.^{272,402,740} Goggles and masks can be effective in further reducing the RSV attack rate among personnel.^{9,238} However, it is unclear whether masks and eye protection are effective because they prevent direct deposition of respiratory droplets on the eyes or nose or merely because they reduce the likelihood that staff will rub their eyes or noses with contaminated hands. Covering only the nose and mouth with a mask is probably not very effective.²⁸⁵ The HICPAC isolation guideline recommends use of contact precautions for care of hospitalized patients with RSV and does not require use of a mask.⁶⁶⁸

Some investigators have demonstrated that cohorting infected patients combined with the use of barriers can reduce spread of RSV.^{193,375,452} However, it is not clear whether cohorting by clinical symptoms alone is effective or all admitted patients must be screened for RSV infection to identify children with minimal symptoms who may be excreting the virus. The added value of strict cohorting instead of rigorous use of barrier precautions has not been demonstrated. Universal gloving for all patient contacts during RSV infection has also been advocated; one study found that this policy was also associated with reduced rates of

BOX 244.1 Standard Precautions^a**A. Handwashing**

- Wash hands after touching blood, body fluids, secretions, excretions, and contaminated items, whether gloves are worn or not.
- Wash hands immediately after gloves are removed, between patient contacts, and when otherwise indicated to avoid transfer of microorganisms to other patients or environments.
- It may be necessary to wash hands between tasks and procedures on the same patient to prevent cross-contamination of different body sites.
- Use a plain (nonantimicrobial) soap for handwashing.
- Use an antimicrobial agent or a waterless antiseptic agent for specific circumstances (e.g., control of outbreaks or hyperendemic infections), as defined by the infection control program.

B. Gloves

- Wear gloves (clean, nonsterile gloves are adequate) when touching blood, body fluids, secretions, excretions, and contaminated items.
- Put on clean gloves just before touching mucous membranes and nonintact skin.
- Change gloves between tasks and procedures on the same patient after contact with material that may contain a high concentration of microorganisms.
- Remove gloves promptly after use, before touching noncontaminated items and environmental surfaces, and before going to another patient, and wash hands immediately to avoid transfer of microorganisms to other patients or environments.

C. Mask, Eye Protection, and Face Shield

- Wear a mask and eye protection or a face shield to protect mucous membranes of the eyes, nose, and mouth during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, and excretions.

D. Gown

- Wear a gown (a clean, nonsterile gown is adequate) to protect skin and prevent soiling of clothing during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions.
- Select a gown that is appropriate for the activity and amount of fluid likely to be encountered.
- Remove a soiled gown as promptly as possible, and wash hands to avoid transfer of microorganisms to other patients or environments.

E. Patient Care Equipment

- Handle used patient care equipment soiled with blood, body fluids, secretions, and excretions in a manner that prevents skin and mucous

membrane exposures, contamination of clothing, and transfer of microorganisms to other patients and environments.

- Ensure that reusable equipment is not used for the care of another patient until it has been cleaned and reprocessed appropriately.
- Ensure that single-use items are discarded properly.

F. Environmental Control

- Ensure that the hospital has adequate procedures for the routine care, cleaning, and disinfection of environmental surfaces, beds, bedrails, bedside equipment, and other frequently touched surfaces, and ensure that these procedures are followed.

G. Linen

- Handle, transport, and process used linen soiled with blood, body fluids, secretions, and excretions in a manner that prevents skin and mucous membrane exposure and contamination of clothing and that avoids transfer of microorganisms to other patients and environments.

H. Occupational Health and Bloodborne Pathogens

- Take care to prevent injuries when using needles, scalpels, and other sharp instruments or devices; when handling sharp instruments after procedures; when cleaning used instruments; and when disposing of used needles.
- Never recap used needles or otherwise manipulate them using both hands or any other technique that involves directing the point of a needle toward any part of the body; rather, use a one-handed scoop technique or a mechanical device designed for holding the needle sheath.
- Do not remove used needles from disposable syringes by hand, and do not bend, break, or otherwise manipulate used needles by hand.
- Place used disposable needles and syringes, scalpel blades, and other sharp items in appropriate puncture-resistant containers, which are located as close as practical to the area in which the items were used, and place reusable syringes and needles in a puncture-resistant container for transport to the reprocessing area.
- Use mouthpieces, resuscitation bags, or other ventilation devices as an alternative to mouth-to-mouth resuscitation methods in areas where the need for resuscitation is predictable.

I. Patient Placement

- Place a patient who contaminates the environment or who does not (or cannot be expected to) assist in maintaining appropriate hygiene or environmental control in a private room.
- If a private room is not available, consult with infection control professionals regarding patient placement or other alternatives.

^aStandard precautions apply to all patients, regardless of their diagnosis or presumed infection status. Standard precautions apply to any planned or potential contact with blood; all body fluids, secretions, and excretions except sweat, regardless of whether they contain visible blood; nonintact skin; and mucous membranes.

From Siegel JD, Rhinehart E, Jackson M, et al. *Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Healthcare Settings 2007*. Centers for Disease Control and Prevention, Healthcare Infection Control Practices Advisory Committee, 2007. Available at: <http://www.cdc.gov/hicpac/2007IP/2007isolationPrecautions.html>.

central line–associated bloodstream infection (CLABSI).⁷⁸¹ The role of palivizumab as routine seasonal prophylaxis or as postexposure prophylaxis for high-risk patients has been examined in uncontrolled studies with generally positive but not conclusive results.^{191,272,350,384,531}

Multidisciplinary programs to promote awareness of the potential for transmission of RSV and optimize the use of prevention measures using all or various combinations of these strategies. They have demonstrated effectiveness in reducing the incidence of health care–associated RSV infection.^{15,272,348,400,402,446}

HCAIs due to parainfluenza virus and human metapneumovirus are similar to RSV in their epidemiology and prevention.^{282,332,498,517} Health care–associated influenza is a common cause of intercurrent

fever in hospitalized children during epidemic periods,^{283,743} and outbreaks in neonatal ICUs have been described.^{157,506,748} Asthma was identified as a risk factor for health care–associated seasonal influenza.⁴⁰¹ Although the 2009–10 pandemic of H1N1 influenza raised concerns about the potential for increased spread of influenza in health care facilities, the risk for transmission among hospitalized children appeared to be no different from that for seasonal influenza,^{218,541} perhaps because of heightened awareness and more rigorous use of barrier precautions.

The modes of transmission of influenza have not been precisely defined. Although direct, indirect, and droplet contact are likely to be important, the potential for airborne transmission and the relative contributions of these various modes of transmission in health care

BOX 244.2 Transmission-Based Precautions^a**Airborne Precautions****A. Patient Placement**

- Place the patient in a private room that has monitored negative air pressure in relation to the surrounding areas; 6–12 air changes per hour; and appropriate discharge of air outdoors or monitored high-efficiency filtration of room air before the air is circulated to other areas in the hospital.
- Keep the room door closed and the patient in the room.
- When a private room is not available, place the patient in a room with a patient who has active infection with the same microorganism, unless otherwise recommended, but with no other infection.
- When a private room is not available and cohorting is not desirable, consultation with infection control professionals is advised before patient placement.

B. Respiratory Protection

- Wear respiratory protection when entering the room of a patient with known or suspected infectious pulmonary tuberculosis.
- A susceptible person should not enter the room of patients known or suspected to have measles (rubeola) or varicella (chickenpox) if other immune caregivers are available.
- If susceptible people must enter the room of a patient known or suspected to have measles or varicella, they should wear respiratory protection.
- People immune to measles or varicella need not wear respiratory protection.

C. Patient Transport

- Limit the movement and transport of the patient from the room to essential purposes only.
- If transport or movement is necessary, minimize patient's dispersal of droplet nuclei by placing a surgical mask on the patient if possible.

D. Additional Precautions for Preventing Transmission of Tuberculosis

- Consult the CDC Guidelines for Preventing the Transmission of Tuberculosis in Health-Care Facilities for additional prevention strategies.

Droplet Precautions**A. Patient Placement**

- Place the patient in a private room.
- When a private room is not available, place the patient in a room with a patient who has active infection with the same microorganism but no other infection.
- When a private room is not available and cohorting is not achievable, maintain spatial separation of at least 3 feet between the infected patient and other patients and visitors.
- Special air handling and ventilation are not necessary, and the door may remain open.

B. Mask

- Wear a mask when working within 3 feet of the patient. (Logistically, some hospitals may want to implement wearing of a mask to enter the room.)

C. Patient Transport

- Limit the movement and transport of the patient from the room to essential purposes only.

- If transport or movement is necessary, minimize patient dispersal of droplets by placing a surgical mask on the patient, if possible.

Contact Precautions**A. Patient Placement**

- Place the patient in a private room.
- When a private room is not available, place the patient in a room with a patient who has active infection with the same microorganism but no other infection.
- When a private room is not available and cohorting is not achievable, consider the epidemiology of the microorganism and the patient population when determining patient placement. Consultation with infection control professionals is advised before patient placement.

B. Gloves

- Wear gloves (clean, nonsterile gloves are adequate) when entering the room.
- During the course of providing care for a patient, change gloves after having contact with infective material that may contain high concentrations of microorganisms (i.e., fecal material and wound drainage).
- Remove gloves before leaving the patient's environment, and wash hands immediately with an antimicrobial agent or a waterless antiseptic agent.
- After glove removal and handwashing, ensure that hands do not touch potentially contaminated environmental surfaces or items in the patient's room to avoid transfer of microorganisms to other patients or environments.

C. Gown

- Wear a gown (a clean, nonsterile gown is adequate) when entering the room if you anticipate that your clothing will have substantial contact with the patient, environmental surfaces, or items in the patient's room or if the patient is incontinent or has diarrhea, an ileostomy, a colostomy, or wound drainage not contained by a dressing.
- Remove the gown before leaving the patient's environment.
- After gown removal, ensure that clothing does not contact potentially contaminated environmental surfaces to avoid transfer of microorganisms to other patients or environments.

D. Patient Transport

- Limit the movement and transport of the patient from the room to essential purposes only.
- If the patient is transported out of the room, ensure that precautions are maintained to minimize the risk for transmission of microorganisms to other patients and contamination of environmental surfaces or equipment.

E. Patient Care Equipment

- When possible, dedicate the use of noncritical patient care equipment to a single patient (or a cohort of patients infected or colonized with the pathogen requiring precautions) to avoid sharing between patients.
- If use of common equipment or items is unavoidable, adequately clean and disinfect them before use for another patient.

F. Additional Precautions for Preventing the Spread of Vancomycin Resistance

- Consult the Healthcare Infection Control Practices Advisory Committee (HICPAC) report on preventing the spread of vancomycin resistance for additional prevention strategies.

^aTransmission-based precautions are followed when indicated in addition to standard precautions.

From Siegel JD, Rhinehart E, Jackson M, et al. *Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Healthcare Settings 2007*. Centers for Disease Control and Prevention, Healthcare Infection Control Practices Advisory Committee, 2007. Available at: <http://www.cdc.gov/hicpac/2007IP/2007isolationPrecautions.html>.

facilities and the potential differences in transmission of seasonal versus pandemic influenza remain unclear.¹⁰⁶ For seasonal influenza, the CDC recommends use of droplet precautions, with the use of respiratory protection equivalent to a fitted N95 filtering facepiece respirator or equivalent N95 respirator during aerosol-generating procedures (<http://www.cdc.gov/flu/professionals/infectioncontrol/healthcaresettings.htm>).

Annual influenza vaccination of high-risk individuals and health care workers is important to limit the impact of transmission in health care facilities.¹¹⁶ Issues related to vaccination of health care workers against influenza are discussed later in this chapter (see **Infection Prevention and Control Programs in Health Care Facilities**). Antiviral medications are an adjunct to vaccination for treatment to reduce viral shedding and chemoprophylaxis to prevent infection after exposure.²¹⁹

Health care–associated adenovirus infections occur sporadically throughout the year, and outbreaks of respiratory tract infection and pharyngoconjunctival fever among hospitalized children have been described. Outbreaks in ICUs and units caring for immunocompromised patients have been associated with severe disease and substantial mortality rates.^{473,678,766} In addition to direct and indirect contact, adenovirus may be spread by droplet contact, necessitating the use of droplet and contact precautions.

Health care–associated coronavirus infections may be more common than recognized.^{236,332} Although standard precautions are sufficient for most serotypes of coronavirus, the CDC recommends contact and airborne precautions for MERS and SARS (<http://www.cdc.gov/coronavirus/mers/infection-prevention-control.html>).

Rhinovirus infections are generally mild, although serious lower tract disease has been documented in children with underlying disorders.¹³³ Standard Precautions are sufficient as a control measure in most situations.

Pertussis

Outbreaks of pertussis in hospitals and chronic care institutions are well documented.^{114,220,382,423,661,697,717,738} In many situations, health care workers were responsible for spreading pertussis to hospitalized children.^{114,132,382,423,738} The beneficial impact but high cost of controlling the intrahospital spread of pertussis was illustrated during a large, community-wide epidemic of pertussis in Cincinnati in 1993.¹³⁵

Prevention of health care–associated pertussis depends on the appropriate isolation of children with suspected infection, use of droplet precautions, antimicrobial treatment of confirmed cases to minimize the potential for transmission, prompt identification and management of exposed patients and health care workers, and chemoprophylaxis for exposed individuals.^{143,381,668} Hospital staff who have symptoms suggesting pertussis must be evaluated and treated promptly, and infected individuals should be excluded from work for at least the first 5 days of the recommended course of treatment. Health care workers should receive booster doses of pertussis vaccine (i.e., tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis [Tdap]) to help prevent transmission in health care facilities.¹¹⁶

Gastrointestinal Viruses

Rotavirus is a common cause of endemic and epidemic health care–associated gastrointestinal virus infection.^{88,156,258,588,602,680,745} The risk of HCAs is closely associated with hospitalization during seasonal outbreaks, young age, and the length of hospitalization.^{88,145,178,745} The risk for transmission from infected children is enhanced because infected children may shed the virus in their stool for many days after symptoms resolve, asymptotically infected patients also may shed virus, and the virus can survive for extended periods on environmental surfaces.^{26,145,239,636,770}

The primary mode of transmission is indirect contact with the contaminated hands of caregivers, and scrupulous adherence to contact precautions and appropriate disinfection of environmental surfaces are critically important.^{678,749} The use of rotavirus vaccine appears to have decreased the risk of health care–associated rotavirus concomitant with reductions in the numbers of children hospitalized due to community-acquired infection.^{24,789}

Health care–associated norovirus infection—most often due to genogroup II.4 that can cause more severe disease—is a major problem, although wards with elderly populations have been affected more

significantly than pediatric wards.^{181,472} Contamination of environmental surfaces is particularly common and contributes to transmission.^{503,544} A HICPAC isolation guideline recommends use of contact precautions and appropriate disinfection of environmental surfaces, with additional recommendations to be considered in outbreak situations.⁴⁴⁷

Other intestinal viruses have been documented to cause endemic and epidemic nosocomial gastrointestinal infection, including enteric adenoviruses,^{156,373} caliciviruses,⁶⁹⁴ astroviruses,^{177,383} and toroviruses.³³³ Contact precautions should be used to prevent transmission of these enteric pathogens.⁶⁶⁸

Clostridium Difficile

Toxin-producing *C. difficile* acquired in the community may be spread in health care settings, although this is difficult to distinguish from spread of *C. difficile* from reservoirs in the health care facility such as infected patients or the health care environment. *C. difficile* infection is discussed later (see **Health Care–Associated Infections Related to Special Pathogens**).

Other Gastrointestinal Bacteria

Gastrointestinal bacterial pathogens, such as *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *Escherichia coli*, and *Vibrio cholerae*, may cause outbreaks of health care–associated diarrhea in areas where gastrointestinal infections caused by these organisms are endemic.* However, they are so uncommon in modern health care facilities that in the absence of an outbreak, the yield of routine stool cultures in the evaluation of health care–associated diarrhea is extremely low.^{81,149,784}

Varicella Zoster Virus

Outbreaks of health care–associated varicella in hospitals have been documented in numerous reports.^{233,276,404,642} The reports demonstrate conclusively that varicella can be transmitted by the airborne route, although spread by direct and droplet contact may well be more efficient. A study that used a polymerase chain reaction (PCR) assay detected airborne virus in the hospital rooms of patients with active infection and in air samples obtained in the hallway just outside the patients' negative-pressure isolation rooms.⁶³⁷

Transmission of varicella can be minimized if infected patients are cared for using airborne precautions in single rooms with separate exhaust systems and negative air pressure relative to the hallway.^{21,668} Contact precautions to prevent direct and indirect contact transmission (i.e., gloves and gowns) are also important. Because infected people are infectious for 24 to 48 hours before distinctive symptoms and signs appear, prompt recognition and isolation of patients and visitors who may be in the contagious phase of varicella is critical. Caregivers who are not immune to varicella should not care for these patients.

Options for postexposure prophylaxis, including passive immunization and use of varicella vaccine and acyclovir, are discussed in the American Academy of Pediatrics' *Red Book*.¹⁸⁷ Hospitalized exposed children should remain in isolation from day 8 to day 21 after exposure. If passive immunization is administered, isolation should be continued until day 28 after exposure.¹⁶

The use of varicella vaccine has diminished the risk for health care–associated varicella by decreasing the number of children hospitalized with varicella, reducing the size of the pool of susceptible children in hospital wards, and providing protective immunity to health care workers who did not have a history of prior infection.¹¹⁶ However, incompletely vaccinated children and health care workers and people who develop breakthrough infection pose a risk for transmission.

Cytomegalovirus

Two studies using molecular typing techniques have documented probable patient-to-patient spread of cytomegalovirus (CMV) in a neonatal ICU and a chronic care unit.^{176,693} In both situations, the infected children had been in close proximity and were cared for by common caregivers for extended periods.

The risk of CMV transmission from infected patients to health care workers is very low. A meta-analysis of studies that examined the risk

*References 48, 98, 103, 203, 252, 302, 349, 485, 587, 617, 654, 702, 741.

of CMV among pediatric nurses indicates that CMV infection in this population occurs at a rate that is comparable to that for control populations (i.e., women of comparable age who are not nurses).⁷ A subanalysis of these data suggests that nursery nurses may have a slightly higher rate of infection than control populations.⁷ However, studies of CMV infection in nursery nurses that involved molecular typing of CMV isolates showed that the infected nurses did not acquire CMV from the infants in their care⁷ and presumably contracted their infections from children in their own households, through sexual contact, or from other community sources.

Given the frequency of asymptomatic CMV excretion from children (e.g., approximately 1% of newborns excrete the virus), health care workers should assume that any child may be excreting virus and should practice hand hygiene and use of standard precautions as a part of routine patient care.⁶⁶⁸ Additional interventions are not indicated, and pregnant staff members do not need to be given special assignments.

Herpes Simplex Virus

Health care–associated transmission of herpes simplex virus (HSV) type 1 to neonates has been confirmed through studies using molecular typing.^{290,422,629,742} Direct contact transmission from a hospital worker with herpes labialis and indirect contact transmission from one infected neonate to another were the most likely routes, although transmission from an asymptomatic parent or caregiver was possible.

Health care–associated HSV infections among health care workers, patients, and family members have been described in ICUs.^{6,559} Herpetic whitlow has been observed among nurses, presumably as a result of direct transmission during suctioning of oral and respiratory secretions from infected patients.⁶ The use of standard precautions, particularly the use of gloves during contact with oral and respiratory sections, and hand hygiene is adequate to prevent transmission of HSV.⁵⁴⁷

Measles, Mumps, and Rubella Viruses

Transmission of measles in health care facilities remains a threat, and hospitals can serve as nidi for community-wide infection.^{74,118,115,129} Measles is transmitted by airborne droplet nuclei, as demonstrated by an outbreak in a pediatrician's office.⁵⁹²

Prevention of health care–associated measles hinges on the prompt recognition of infected or potentially infected patients and placement of these patients in isolation rooms with negative air pressure relative to that of the hallway.^{118,668} Despite prompt recognition, the identification and management of exposed patients, their family members, and health care workers is time consuming and expensive.⁷⁶² Prophylactic vaccination of exposed susceptible individuals within 3 days of the exposure reliably prevents measles, whereas administration of immune globulin within 3 days attenuates disease but does not guarantee that the exposed individual will not develop contagious infection.¹⁸⁶ To avoid outbreaks of measles among health care workers, health care facilities should require new employees involved in patient care to provide evidence of immunity or appropriate vaccination or to receive vaccination with measles vaccine or measles-mumps-rubella (MMR) vaccine.^{116,376}

Outbreaks of health care–associated mumps and rubella have been reported less commonly than measles.^{303,565,703,767} The primary concern about the spread of both infections is the potential for complications in health care workers—mumps orchitis in men and rubella in pregnant staff.

Information regarding the transmission of both viruses is limited, but it probably occurs primarily by droplet contact. Droplet precautions should be observed during close contact with infected patients.⁶⁶⁸ Because transmission of mumps occurs before and within 5 days of parotitis onset, isolation should be imposed during this period.³⁸⁷ Patients with congenital rubella syndrome may excrete large amounts of virus in their urine and respiratory secretions for extended periods. Gowns and gloves should be worn for contact with these patients for the first year of life unless nasopharyngeal and urine cultures are negative by 3 months of age.⁶⁶⁸ There is no known effective postexposure prophylaxis for mumps- or rubella-exposed individuals.

As with prevention of measles, new employees involved in patient care should provide evidence of immunity or appropriate vaccination or receive vaccination with MMR vaccine as a condition of employment.¹¹⁶

Parvovirus B19

The wide spectrum of disease caused by parvovirus B19 coupled with well-documented health care–associated outbreaks of infection has fueled efforts to understand the transmission and control of this virus in hospitals. An experimental study of acute parvovirus B19 infection in normal adults detected virus in respiratory secretions during a period of viremia and systemic symptoms 6 to 13 days after inoculation.²² Detectable virus in respiratory secretions disappeared as viremia and systemic symptoms diminished, and virus was not demonstrable in respiratory secretions when rash, arthralgias, and arthritis occurred several days later.²² From studies of parvovirus B19 infection in health care facilities, it is apparent that the virus can be transmitted by acutely infected patients, probably due to high levels of virus in their blood and respiratory secretions.^{49,216,374,440,560,590} The risk of transmission from chronically infected, immunocompromised patients is less clear; however, from one report, it appears that these patients can transmit infection.⁴⁴⁰

The mode of transmission is not clear but probably involves direct or indirect contact with respiratory secretions or droplet transmission. Droplet precautions should be maintained during contact with infected patients, and gloves should be worn when handling fomites contaminated with respiratory secretions.⁶⁶⁸

Parvovirus B19 has also been transmitted by plasma-derived factor replacement products used to treat hemophilia because the virus is resistant to the viral inactivation processes currently used in the manufacture of these products.^{36,635,691} Screening blood donations for parvovirus B19 using nucleic acid tests has decreased but not eliminated the potential for transmission of the virus through transfusion of plasma-derived factor replacement products.⁶⁹¹

Hepatitis A Virus

In the prevaccination era, hepatitis A virus caused rare but large epidemics in health care facilities.^{34,198,362,522,754} Mildly symptomatic children who excrete virus in their stool can cause widespread transmission, and many secondary cases can occur before the infection is detected and contained.

Controlling a health care–associated hepatitis A outbreak is difficult and may require the assistance of the local health department. To limit the potential for indirect contact transmission, hospitalized infected children should be grouped together. Hand hygiene and use of barrier precautions should be emphasized to prevent direct and indirect contact transmission.⁶⁶⁸ Postexposure prophylaxis, which may involve immune globulin or hepatitis A vaccination depending on age and underlying conditions, should be administered to all exposed, susceptible individuals.¹⁸⁸ Symptomatic health care providers should be furloughed until 1 week after the onset of symptomatic infection or until all susceptible people have received immune globulin.⁷⁰

Enteroviruses

Outbreaks of health care–associated enterovirus have been reported, with most occurring in neonatal nurseries.^{40,65,126,298,317,342,361,386,583,710} As for hepatitis A, hand hygiene and barrier precautions are of paramount importance to prevent transmission, and cohorting of infected infants is prudent.⁶⁶⁸ One report describes the value of early diagnosis using a PCR assay.³¹ The upper respiratory tract may be involved in acute enteroviral infection, but the use of masks by caregivers is not recommended.⁶⁶⁸

Tuberculosis

Health care–associated tuberculosis in pediatric patients occurs almost exclusively as a result of transmission of *Mycobacterium tuberculosis* from infected adults—parents, visitors, and health care workers—to children and other adults.^{35,251,491,521,700,760} Probable transmission from infected children in health care settings has been described.^{471,582} However, the risk of transmission from a child is very small because children infrequently have cavitory disease and consequently have fewer tubercle bacilli in their endobronchial secretions and because young children do not tend to generate aerosols of airborne droplet nuclei.⁶⁹⁶ Nonetheless,

transmission from children can occur as evidenced by extensive transmission from a 9-year-old child with bilateral cavitary disease.¹⁵⁹

The risk of health care–associated tuberculosis in adult hospitals has been minimized by prompt recognition and treatment of pulmonary tuberculosis, adequate isolation of infectious patients in rooms with negative air pressure relative to that of the hallway, and proper use of personal protective equipment.³³⁹ If rooms with appropriate ventilation are unavailable, alternative engineering solutions, such as well-placed and maintained ultraviolet lights, may be useful.³³⁹ Personnel entering the rooms of infected patients should wear respiratory protection devices. Particulate respirators with a National Institute for Occupational Safety and Health (NIOSH) certification of N95 or better satisfy the CDC specifications for these devices.³³⁹ These devices must be fit tested on the individuals using them according to the standards of the Occupational Health and Safety Administration (OSHA).³³⁹

Prompt identification of tuberculosis in parents, visitors, and health care workers in hospitals caring for pediatric patients is essential for reducing the risk for health care–associated tuberculosis in children and is cost saving compared with conducting postexposure follow-up investigations.¹⁵⁴ Health care workers should be screened yearly for evidence of tuberculosis.³³⁹

Invasive Bacterial Infections

Health care–associated transmission of *Neisseria meningitidis* is rare.^{142,208,604} Nonetheless, *N. meningitidis* is spread by droplet transmission, and health care workers should use droplet precautions during the care of patients with suspected meningococcal disease until the patient has completed 24 hours of parenteral antimicrobial therapy.⁶⁶⁸

Microbiology laboratory workers have developed fatal disease after working with cultures of this microorganism.^{122,121} Clinical and research microbiologists who may be exposed routinely to isolates of *N. meningitidis* should receive meningococcal conjugate vaccine and booster doses every 5 years if they remain at increased risk.¹¹⁶

Health care–associated transmission of *Haemophilus influenzae* and *Streptococcus pneumoniae* has been a rare phenomenon.* The risk has likely been diminished substantially with vaccination.

Invasive bacterial infections in neonates, including infections caused by *S. aureus*, group B streptococci, *Citrobacter* spp., and *Enterobacter sakazakii*, are discussed later (see **Health Care–Associated Infections in Special Populations**).

Ectoparasites

Many outbreaks of scabies have been reported from a variety of health care institutions. The presence of crusted scabies, which is associated with defects in cellular immunity, increases the risk for transmission dramatically because of the large number of mites in these lesions.⁴¹³ Although health care–associated transmission of pediculosis is possible, the direct or indirect contact necessary to spread this infection (i.e., head-to-head contact or sharing of combs) is less likely in medical settings than at home.

Intestinal Helminths

Person-to-person transmission of *Enterobius vermicularis* (i.e., pinworm), *Strongyloides stercoralis*, *Hymenolepis nana*, and *Taenia solium* is possible because these microorganisms do not require an intermediate host and because the eggs or larvae excreted in the stool are infectious.⁴¹⁴ However, evidence for health care–associated transmission of these microorganisms is limited.⁴¹⁴

HEALTH CARE–ASSOCIATED INFECTIONS DUE TO INVASIVE DEVICES AND PROCEDURES

HCAIs can occur from contact with intravascular catheters and infusions, respiratory therapy, instrumentation of the urinary tract, and surgical procedures. Children are at risk for other HCAIs related to medical treatments, including infections associated with the receipt of blood products. More is written about these infections in the chapters on common bloodborne pathogens.

Infections Related to Intravascular Catheters and Infusions

Infections related to intravascular catheters may be local or systemic. Local infections may involve the catheter exit site, subcutaneous track of tunneled catheters, or subcutaneous pocket of an implanted catheter.^{483,533} Phlebitis is a common local complication but is usually caused by chemical or mechanical irritation and is less common in children than adults.²⁴⁴ Suppurative thrombophlebitis is rare in children.³⁵⁵ Bloodstream infections related to intravascular catheters can have serious complications, including development of endocarditis, septic thrombophlebitis, and infection at distal sites due to hematogenous seeding, and they independently increase mortality rates, length of stay, and hospital cost.^{211,266,483,533}

Clinical and surveillance definitions for bloodstream infections related to central venous catheters differ, although they are often used interchangeably.^{312,483} Catheter-related bloodstream infections are clinical events that require investigation to establish the catheter as the definitive source of infection (i.e., through quantitative blood cultures, differential time to positivity, or culture of the catheter itself, if removed).⁴⁸⁴

For surveillance purposes, central line–associated bloodstream infection (CLABSI) is the term used by the CDC's National Healthcare Safety Network (NHSN) to capture primary bloodstream infections in patients with central lines.²⁰¹ This definition is simpler for surveillance purposes. There is concern that NHSN definitions may overestimate catheter-related infections among some patients with impaired mucosal integrity in whom bacterial translocation may affect the pathogenesis of bloodstream infections.²²⁷ This led to the development of modified definitions for infections in this subgroup of patients, identified as mucosal barrier injury CLABSI (MBI-CLABSI).^{184,214,650} The CDC's NHSN website (<http://www.cdc.gov/nhsn>) provides updates on NHSN definitions and methods. Although the focus in this chapter is primarily on clinical events related to catheters, most epidemiologic data on bloodstream infections come from the use of surveillance definitions.

Most endemic catheter-associated bloodstream infections in children are associated with central venous catheters.⁴⁵⁵ Peripheral venous catheters, especially catheters made with modern, nonthrombogenic materials, are rarely associated with bloodstream infections,^{244,245,455,665} although few data are systematically collected, and the risk may be underestimated.^{243,734} Peripheral arterial catheters were historically associated with lower infection rates compared with central venous catheters^{200,235}; however, evidence suggests that rates of colonization and infection of these catheters may be similar to those observed for central lines.^{369,439,537,620} The risk for bloodstream infection associated with peripheral arterial catheters appears to be highest among patients with femorally inserted catheters.^{215,436}

The remainder of this section focuses on infections in central venous catheters. With prevention efforts, rates of catheter-associated bloodstream infections in the United States have decreased dramatically; the CDC's NHSN reported a 46% decline in CLABSIs between 2008 and 2013.²⁰¹ However, device-associated infections comprise approximately 25% of all HCAIs reported to NHSN,⁴⁵³ and CLABSIs represent the most common device-associated infection in hospitalized children.²⁰¹ A NHSN report included data from 4567 hospitals from 53 states, territories, and the District of Columbia, of which 82 (1.8%) were dedicated children's or women and children's hospitals.²⁰¹

Rates of bloodstream infection associated with central venous catheters in pediatric ICUs and inpatient wards and with neonatal ICUs are shown in **Table 244.1** and **Fig. 244.1**. Rates of infection are highest among children in hematology/oncology and bone marrow transplantation units.²⁰¹ Catheter-associated infections are also common among children with intestinal failure (i.e., short-gut syndrome) who depend on parenteral nutrition. Among premature infants, infection rates are inversely proportional to birth weight. These data do not distinguish rates of infection associated with specific catheter types nor whether a specific catheter is the source of infection in patients who have multiple catheters in place concurrently.

Gram-positive organisms, including coagulase-negative staphylococci, *S. aureus*, and enterococci are most commonly identified in catheter-associated infections.^{97,465,670,775} Although rates of CLABSI have decreased overall in recent years, the incidence density rate of *S. aureus* CLABSIs

^aData from January to December 2013.^bCentral line–associated bloodstream infections/1000 central line days.Modified from Dudeck MA, Edwards JR, Allen-Bridson K, et al. National Healthcare Safety Network (NHSN) Report, data summary for 2013, device-associated module. *Am J Infect Control*. 2015;43:206–221.**FIG. 244.1** Distribution of central line–associated bloodstream infection rates in level III neonatal intensive care units (ICUs) reported to the National Healthcare Safety Network (NHSN). Box plots of the distribution of central line–associated bloodstream infection rates in neonatal ICUs show the 50th percentile or median (solid squares), 75th percentile (upper bound of each rectangle), and 90th percentile (upper bound of the line extending above each rectangle). The number of participating neonatal ICUs in each of the birthweight classes ranged from 389 to 433. (Modified from Dudeck MA, Edwards JR, Allen-Bridson K, et al. National Healthcare Safety Network [NHSN] report, data summary for 2013, device-associated module. *Am J Infect Control*. 2015;43:206–221.)

among pediatric ICUs in the United States has remained the same.²¹⁷ Identification of gram-negative bacilli, including *Enterobacter* spp., *P. aeruginosa*, *Klebsiella pneumoniae*, and *Escherichia coli*, has increased to approximately one third of reported infections.⁶⁷⁰ *Candida* spp. have also become increasingly prevalent^{670,776} and comprised 15% of reported catheter-associated infections among a collaborative of pediatric ICUs.³²⁰

Antimicrobial resistance is a concern for all common pathogens isolated from bloodstream infections, including *S. aureus* and gram-negative bacilli.^{96,670} Fifty percent of *S. aureus* infections were caused by MRSA in a collaborative of pediatric ICUs.⁵²⁰ Bloodstream infections due to VRE may be more prevalent among high-risk groups such as pediatric oncology patients and should be considered when selecting empiric therapy based on local epidemiology.³⁵³ Non-tuberculous mycobacteria and *Nocardia* spp. also can cause bloodstream infections.¹¹

The four major mechanisms for contamination of intravascular catheters are migration of microorganisms colonizing the skin at the insertion site along the external catheter surface and into the blood vessel (i.e., extraluminal contamination), contamination of the catheter or catheter hub through contact with hands of health care workers (i.e., intraluminal contamination), hematogenous seeding from another focus of infection, and contamination of the infusate.^{151,152,533,534} The first two mechanisms are most important and vary in their contributions to infection depending on the duration of catheterization.⁵⁷⁹ Extraluminal contamination predominates in the first 10 days (likely related to contamination during insertion), whereas the potential for intraluminal contamination increases with duration of catheterization and is most common after 30 days, most likely due to contamination during routine catheter maintenance and use.⁵⁷⁹ Contamination of infusates is relatively uncommon; however, several epidemics have been associated with contaminated intravenous infusions,^{424,425,457,662} medications,^{51,270,457,543} and blood products.¹⁰⁸

Additional pathogenic determinants of bloodstream infection include catheter material, host factors leading to the formation of a fibrin sheath,⁴⁸² and intrinsic virulence of the microorganism. Adherence properties of microorganisms are critical. Production of an extracellular polymeric substance by organisms such as coagulase-negative staphylococci, *S. aureus*, and *P. aeruginosa* leads to formation of a microbial biofilm in which microorganisms can become embedded and proliferate relatively protected from host defenses and antimicrobial agents.^{5196,321,478} *Candida* spp. also routinely produce biofilms, particularly in the presence of glucose-containing fluids.⁸²

Risk factors for catheter-related bloodstream infection include heavy colonization of the skin at the catheter exit site^{151,152,534,580} or catheter hub,^{170,420} longer duration of insertion (>3 days),^{153,244,245} prolonged hospitalization before catheterization,⁴⁶⁹ presence of multiple concurrent central venous catheters,¹⁴⁴ substandard catheter care,⁴⁶⁹ and host factors (e.g., neutropenia, prematurity),⁴⁶⁹ including an extant mural or atrial thrombus.^{151,152,534} The level and composition of nurse staffing have also been associated with bloodstream infections in adult surgical ICUs. Low ratios of nurses to patients and regular nurses (as opposed to pool nurses to patients) have been associated with higher risks of bloodstream infections.^{230,600}

Dedicated pediatric studies are limited, but age younger than 2 years, duration of catheterization (>7 days), and receipt of parenteral nutrition or blood transfusions have been independently associated with catheter-associated bloodstream infections in pediatric ICU patients.^{175,210,268,469,520,779} A study of children at a tertiary care center found that catheter breakage was associated with significantly increased risk of bloodstream infection within 30 days of repair.⁴⁴³ Additional novel risk factors identified in single studies include presence of a gastrostomy tube, nonoperative cardiovascular disease, ICU catheter placement,⁷⁷⁹ and catheter placement at an external facility before hospital transfer.³⁷⁷ Among pediatric oncology patients, placement of the catheter within 1 month, previous bacteremia in any central line, frequent platelet transfusions, and host factors, including recent neutropenia, relapsed malignancy, and bone marrow transplantation within the prior 100 days, have been associated with an increased risk of bloodstream infection.^{19,353,354,599} Infusion of parenteral nutrition with lipids increases the risk of infection with coagulase-negative staphylococci and *Candida* in neonates.^{32,87,228,623}

Among central venous catheters, nontunneled (percutaneously inserted) catheters account for most catheter-associated bloodstream infections, whereas totally implantable catheters carry the lowest risk,^{316,398,495,657,698,769,778} although these comparisons may be confounded by several factors, including age and underlying severity of illness.^{32,87,327,769,778} Tunneled catheters carry a lower infection risk

compared with nontunneled catheters because a cuff prevents migration of microorganisms into the catheter tract. However, in a study of children with acute lymphoblastic leukemia undergoing induction chemotherapy, the catheter type (i.e., tunneled vs. nontunneled) used at the time of diagnosis had no impact on subsequent risk of bloodstream infection in this high-risk group.⁵³

Peripherally inserted central (venous) catheters (PICCs) are used commonly in children, but data suggest the risk of PICC-associated infections in ICUs approaches that of centrally inserted venous catheters.^{134,469} Duration of catheter dwell increases the risk of PICC-associated infection among neonates, although this finding has been inconsistent between studies.^{268,494,655} Rates of infection are similar for catheters placed in the umbilical vein or artery.³⁹²

Catheter insertion site influences infection risk for adults, likely due to the density of local skin microorganisms. A meta-analysis showed that catheters inserted into the internal jugular vein carry a higher risk of colonization and infection compared with subclavian catheters, whereas femorally inserted catheters carry the highest risk, although the investigators suggested that interpretation might be limited by study heterogeneity and limitations in study design.⁵⁴⁹ A Cochrane Review concluded that subclavian catheters were associated with less colonization and fewer thrombotic complications than femoral catheters in short-term catheterization, but no difference was found between subclavian and internal jugular venous catheters.⁵⁵ Femoral catheters have not been associated with higher rates of colonization and infection among children.^{469,520,594}

Several methods have been used to identify the catheter as the source of infection, although no microbiologic gold standard for diagnosis of catheter-related bloodstream infection exists.⁴² Proposed methods include collection of paired blood cultures from the catheter and a peripheral vein before starting therapy.⁴⁸³ If a peripheral sample cannot be obtained, at least two samples should be drawn through different catheter lumens. If the catheter is removed because of suspected infection, catheter tip culture can be performed to determine whether it is colonized. Semi-quantitative (roll-plate) or quantitative catheter culture techniques (i.e., luminal flushing or sonication) are the most reliable modalities and are preferred over qualitative broth cultures.^{460,580,619,662,669}

Clinical criteria for definitive diagnosis of catheter-related bloodstream infections have been published⁴⁸³ and require positive percutaneous culture results with concordant microbial growth from the catheter tip or catheter-drawn cultures that meet criteria for quantitative culture or differential time to positivity.⁴⁸³ Quantitative blood cultures are the most accurate, but the differential time-to-positivity technique can be almost as sensitive (provided the same volume of blood is used to inoculate both blood culture bottles) and is less labor intensive.⁶¹⁹ Because peripheral blood cultures are drawn less frequently in children due to difficulty in obtaining peripheral specimens or concerns about drawing large blood volumes, the catheter is often implicated presumptively if no other source of infection is identified. This assumption has implications for management (including catheter removal) and is discussed further later.⁴⁸³

Empiric antimicrobial therapy for children with suspected bloodstream infection is similar to that for adults. Choice of therapy should be based on severity of illness, the nature and severity of underlying conditions, and epidemiology and susceptibility patterns of local pathogens. The clinical practice guideline cited previously contains detailed management recommendations.⁴⁸³ In most cases, empiric therapy should include coverage of gram-positive and gram-negative bacteria. Because of the increased prevalence of MRSA across institutions, vancomycin is often included. Empiric combination therapy for multidrug-resistant, gram-negative bacilli such as *P. aeruginosa* should be added for patients who are severely ill, neutropenic, or known to be colonized with these organisms. Empiric antifungal therapy may be considered for septic patients with risk factors for candidemia, including receipt of parenteral nutrition, prolonged use of broad-spectrum antibiotics, hematologic malignancy, receipt of bone marrow or a solid organ transplant, or known colonization with *Candida* spp. After culture information is available, treatment can be tailored or discontinued as appropriate.

There is substantial evidence that most uncomplicated bloodstream infections in children can be treated effectively without catheter

removal.^{221,483,769} However, catheter removal should be strongly considered for difficult-to-treat bacteria, such as *S. aureus*, *P. aeruginosa*, and mycobacteria.⁴⁸³ Treatment of catheter-associated fungemia without catheter removal has a relatively low success rate and may be associated with higher mortality rates.^{165,246,484} Although a retrospective study of adults with catheter-associated candidemia found no difference in outcomes between early and late catheter removal, it did not address long-term outcomes such as recurrence.⁵²⁶ This finding will require further consideration in future practice guidelines. Catheters should be removed immediately in patients with severe sepsis, embolic phenomena, septic thrombophlebitis, or endocarditis or if infection continues despite more than 72 hours of targeted therapy.

Clinical practice guidelines review the use of antibiotic lock therapy in the treatment of catheter-related bacteremia when catheter salvage is the goal.⁴⁸³ The concept behind lock therapy is that organisms embedded in biofilms on intraluminal surfaces of long-term catheters may be killed more effectively by antibiotic concentrations 100 to 1000 times higher than standard concentrations of therapeutic parenteral antibiotics.⁴⁸³ Antibiotic lock solutions are typically mixed with heparin in sufficient volumes to fill the lumen, allowed to dwell, and then removed. This approach is recommended in conjunction with systemic therapy for selected organisms. Lock therapy is not recommended for infections due to *S. aureus* and *Candida* spp. unless unusual extenuating circumstances are identified.⁴⁸³ Use of adjunctive urokinase or other thrombolytic agents is not recommended.^{30,397,483}

Duration of therapy varies by pathogen type but is typically 7 to 14 days.⁴⁸³ With catheter removal, shorter courses (5–7 days) may be appropriate for uncomplicated infections with less virulent organisms such as coagulase-negative staphylococci. Persistently positive blood cultures despite targeted therapy or recrudescence of infection shortly thereafter should prompt catheter removal. Catheter removal from patients with persistent fever but no positive culture results and no evidence of infection elsewhere is controversial and should be approached on a case-by-case basis.

Some success has been reported in treating uncomplicated exit site infections without catheter removal. A trial of combined local and systemic antimicrobial treatment is warranted before a decision to remove the catheter is made. In contrast, treatment outcomes of tunnel or pocket infections usually are poor if the catheter is retained.^{483,769}

A guideline for the prevention of catheter-related infections was updated,⁴⁶⁹ and several reviews have summarized novel technologies for prevention of these infections.^{151,304,580} Significant improvement in infection rates has been achieved within the context of organized initiatives and the use of care bundles for catheter insertion and maintenance. Key preventive measures are emphasized in this discussion.

Use of intravascular catheters should be limited to only when necessary. Reducing exposure to central venous catheters is one of the simplest ways to reduce bloodstream infection risk. Adherence to preventive measures during catheter insertion has significantly reduced bloodstream infections in adults, and these practices are often applied using insertion bundles.^{52,577,752} Use of an insertion checklist and a fully stocked catheter cart or kit is recommended to ensure optimal practices are followed.⁴⁶⁹ Key preventive measures during insertion include performance of hand hygiene and use of maximal sterile barrier precautions (e.g., sterile gowns, gloves, drapes).^{469,581} Use of an alcoholic chlorhexidine antiseptic is preferred over povidone-iodine.^{125,151,243,458,469} The catheter site should be covered with sterile gauze or a sterile, transparent, semipermeable dressing.⁴⁶⁹ Routine application of topical antimicrobial agents is not recommended,^{151,533,534} except for hemodialysis catheters.⁴⁶⁹

Ongoing preventive measures during catheter maintenance are critical. A pediatric quality improvement collaborative showed that maximizing compliance with insertion bundles was insufficient to reduce bloodstream infection rates in pediatric ICUs, underscoring the importance of scrupulous practices related to routine catheter use and maintenance.^{338,347,490,648,774} Many improvement initiatives over the past decade have advocated maintenance care bundles—simultaneous implementation of multiple preventive practices to achieve maximal reductions in infections.²⁰⁷ These bundles include daily assessment of catheter necessity and adherence to aseptic technique during catheter hub and catheter site care. Catheter hubs are common sites of catheter colonization; hubs

should be cleansed using mechanical friction during each access with 70% ethanol, alcoholic chlorhexidine, or povidone-iodine.⁴⁶⁹ Numerous studies have demonstrated the benefit of daily chlorhexidine bathing in reducing CLABSI in adult settings^{190,499,509,572} and in pediatric and neonatal ICUs.^{492,578} This practice is now recommended for all ICU patients with central venous catheters.⁴⁶⁹ The US Food and Drug Administration recommends care in the use of chlorhexidine for skin antisepsis for premature infants or infants younger than 2 months of age because products with this chemical can cause irritation or chemical burns.⁸

Prevention guidelines also highlight the importance of minimizing catheter manipulation and provide detailed guidance for maintaining closed systems and when to change infusion sets.^{469,534} Minimizing the frequency of catheter access is a common preventive strategy at many hospitals, although there are few data to support the practice.

Special approaches to prevention are recommended when infection rates remain unacceptably high despite adherence to basic preventive practices. These interventions include use of chlorhexidine-containing dressings^{102,242,291,415,456,728} for central venous catheters in patients older than 2 months⁴⁶⁹ and the use of antiseptic- or antibiotic-impregnated catheters.^{151,533,534,580} Although most studies of impregnated catheters have considered adults, pediatric data are mounting,^{60,128} including a randomized, controlled trial enrolling pediatric ICU patients that found the use of antibiotic-impregnated catheters significantly reduced rates of bloodstream infection compared with standard central venous catheters.²⁶⁰ However, the anti-infective effect of these catheters is not permanent and may be limited to a relatively short period after insertion. Their long-term impact on antimicrobial resistance has not been evaluated, although prospective studies suggest that this risk is likely low.^{533,633}

Multiple controlled studies have evaluated the use of antibiotic or antiseptic locks for the prevention of catheter-related bloodstream infections.⁴⁹⁴ Numerous studies of antimicrobial lock therapy have demonstrated significant reductions in bloodstream infection risk,^{241,534,539,780} including a meta-analysis of randomized clinical trials that showed a 69% reduction in CLABSIs among a variety of patient populations, including hemodialysis patients, adult and pediatric oncology patients, critically ill neonates, and patients receiving parenteral nutrition.⁷⁸³ Multiple antibiotic and antiseptic lock solutions have been evaluated. Due to concerns regarding emergence of antimicrobial resistance in exposed organisms, antimicrobial lock therapy is recommended for patients at highest risk, including those with long-term hemodialysis catheters, patients with limited venous access and history of recurrent infection, and those at risk for severe sequelae from infection.⁴⁶⁹

Infections Related to Respiratory Therapy

Most infections related to respiratory therapy are associated with mechanical ventilation. Infections related to the use of other respiratory equipment, such as small-volume medication nebulizers, have also been described, although usually in the setting of epidemics related to the use of contaminated equipment.^{68,150,470,497} This discussion focuses primarily on ventilator-associated events or complications.

Major infections include tracheitis, tracheobronchitis, and pneumonia. Mechanical ventilation may also increase the risk of sinusitis and otitis media among nasally intubated patients because nasotracheal tubes interfere with normal drainage of the sinus ostia and eustachian tubes.^{54,273} Most of the clinical and surveillance data exist for ventilator-associated pneumonia (VAP).

VAP has been reported in 9% to 27% of intubated patients and is associated with prolonged ventilation, increased length of stay, higher mortality rates, and increased hospital costs.^{274,346,534} Estimated rates of pneumonia for ventilated adults have been lower in recent years, ranging from 5% to 15%.³⁶⁵ VAP rates for children in pediatric and neonatal ICUs are available from the CDC's 2013 NHSN report.²⁰¹ Similar to catheter-associated bloodstream infections, infection rates among neonates are inversely proportional to birth weight.²⁰¹ Comparisons between adult and pediatric rates of infection are limited due to recent changes in surveillance definitions. The VAP surveillance definition no longer applies to adult patients and was replaced by ventilator-associated events (VAEs) in 2013.²⁰¹ VAE definitions include criteria for

ventilator-associated conditions (VACs), infection-related ventilator-associated conditions (IVACs), possible pneumonia, and probable pneumonia.³⁶⁵

The CDC convened a Neonatal and Pediatric VAE working group to modify the VAE definition for use in children.¹³⁹ Until new definitions are finalized and available for use, VAP surveillance continues for pediatric critical care locations,²⁰¹ and the term VAP continues to be used to describe clinical events involving pneumonia in ventilated patients. Aside from NHSN reports of infection rates, dedicated studies of VAP in infants and children are limited, although several reviews have summarized the existing pediatric literature.^{223,575,744,777} Most of the information discussed is from adult studies.

Most cases of VAP are bacterial in origin and polymicrobial. The duration of mechanical ventilation before symptom onset is an important determinant of the most likely pathogens. Early pneumonia (<4 days) is more likely caused by antibiotic-sensitive community pathogens, such as *S. pneumoniae* and *Haemophilus* spp., whereas late infections (>4 days) are more often related to antibiotic-resistant organisms.^{18,323,346,533} This difference reflects the frequency of exposure to prior antimicrobial therapy and the epidemiology of local ICU pathogens. The distinction may be less meaningful for patients who are frequently admitted to health care settings.

Major pathogens include gram-positive and gram-negative bacteria; *S. aureus* (including MRSA) and *P. aeruginosa* are isolated most frequently.^{14,271,323} Other pathogens include *Streptococcus* spp., Enterobacteriaceae, and *Acinetobacter* spp.^{250,323,596} Risk factors for infection with multidrug-resistant pathogens include prior intravenous antibiotics within 90 days, hospitalization for 5 or more days before diagnosis, septic shock, preceding acute respiratory distress syndrome (ARDS), and acute renal replacement therapy before infection onset.³⁴⁶ Anaerobic bacteria are uncommonly implicated³²³ but may play a role in polymicrobial infections, particularly when pneumonia results from aspiration. Nosocomial viruses and fungi rarely cause pneumonia in immunocompetent hosts. Although *Candida* spp. are sometimes isolated from lower respiratory tract samples, they are rarely the primary cause of pneumonia.¹⁸

VAP occurs when bacteria invade the pulmonary parenchyma of a patient receiving mechanical ventilation.¹⁴¹ This process is directly linked to aspiration of oropharyngeal or gastric secretions that harbor potentially pathogenic organisms.^{18,323} Colonization with pathogenic bacteria is facilitated by several factors, including enhanced bacterial adherence to mucosal surfaces in severely ill or debilitated patients, bacterial overgrowth of the stomach when acid-suppressing medications are used, and reductions in microbial diversity and pathogen selection due to antibiotic exposure.^{535,707}

Endotracheal tubes interfere with normal protective airway reflexes and prevent effective coughing. Contaminated secretions pool and leak around the endotracheal tube. This process is exacerbated during changes in position or deflation of the subglottic cuff of the endotracheal tube cuff. Bacterial biofilms also form on the inner surface of the tube, providing a direct route for microbial invasion into the lower airway.⁵³⁵

Regurgitation of bacteria from the stomach into the pharynx can provide another route for bacteria into the airway. Normal gastric pH prevents heavy contamination of stomach contents, but bacteria proliferate when stomach acid is neutralized by antacids or histamine-2 (H_2) blockers. However, the degree to which gastric colonization contributes to risk for pneumonia is unclear.⁷⁰⁷ Other potential pathways for infection include use of contaminated equipment or medications, often in outbreak settings,⁴³⁸ and bacteremia with hematogenous spread.¹⁸

After pathogens enter the lower airway, host defenses are important in determining whether infection results. Diseases that compromise mucociliary clearance or the ability of the immune system to contain and inactivate pathogens dramatically increase infection risk.

Risk factors for VAP in adults include host factors that increase susceptibility to pneumonia, such as advanced age, underlying chronic lung disease, and immunosuppression; treatment factors that enhance colonization of the oropharynx or stomach with pathogenic bacteria; factors that promote reflux of gastric contents and aspiration into the lower airway, such as depressed mental status, supine positioning,

nasogastric tubes, and enteral feeding; conditions that increase the duration of ventilation; and factors that hinder adequate pulmonary toilet, such as thoracic or abdominal surgery and immobilization.⁷⁰⁷

Although dedicated pediatric studies are limited, it is likely that many of the adult risk factors are also important for children. Prospective studies of critically ill children found that a genetic syndrome, postsurgical admission diagnosis, duration of stay in a pediatric ICU, prior antibiotic therapy, use of narcotic medications, enteral feeds, reintubation, and transport out of the ICU were independently associated with VAP.^{14,212,249,274,385,554,695} Trauma,⁷⁰⁹ female gender,⁶⁹⁵ tracheostomy,⁵⁵⁴ and gastroesophageal reflux disease² have also been associated with VAP in children in single studies.

The diagnosis of VAP can be challenging. Clinical diagnosis requires evaluation of a combination of clinical, radiographic, and microbiologic data. Relevant clinical findings include fever, leukocytosis or leukopenia, purulent secretions, and worsening gas exchange. Auscultation is often hindered by sounds of the ventilation system itself (particularly with high-frequency ventilation), and a variety of underlying pulmonary diseases and conditions (e.g., fluid overload) may produce sounds indistinguishable from those present in pneumonia. Radiographic findings include new or progressive pulmonary infiltrates, cavitation, air bronchograms, and pneumatoceles. Air bronchograms are the most sensitive for detecting pneumonia,⁷⁴⁴ but chest radiograph findings have only limited specificity, because significant overlap exists between pneumonia and other pulmonary conditions.

Microbiologic data are important in the diagnosis and in guiding subsequent treatment. Samples of lower respiratory tract secretions and blood cultures should be obtained for all patients with suspected VAP. Tracheal aspirates can be misleading in an asymptomatic patient because endotracheal tubes are often colonized with potential pathogens.²⁶¹ Several invasive and noninvasive methods for obtaining respiratory specimens have been evaluated.^{90,666,724} Current clinical practice guidelines recommend noninvasive sampling (i.e., endotracheal aspiration) with semiquantitative cultures for diagnosis³⁴⁶ because current evidence does not show a difference in outcomes between sampling methods.³⁴⁶ Gram stains are helpful in ruling out pneumonia when results are negative, but they have very poor positive predictive value⁵³⁸ because localized irritation or superficial infection of the trachea can produce purulent secretions.

Empiric therapy for VAP should be based on the duration of intubation and hospitalization, prior or current antibiotic therapy, severity of clinical disease, nature and severity of underlying conditions, and epidemiology and resistance patterns of local pathogens. Several adult studies have shown that delayed initiation or inappropriate antibiotic therapy is associated with poor outcomes.¹⁸ Initial broad-spectrum therapy with adequate coverage of *S. aureus* (and possibly MRSA), *P. aeruginosa*, and other gram-negative bacilli, as guided by local epidemiology, usually is appropriate and can be narrowed based on subsequent culture data and clinical and radiographic findings.^{18,346}

Prolonged treatment of patients for whom the diagnosis is questionable should be avoided because this practice may lead to endotracheal colonization with antimicrobial-resistant bacteria. Treatment duration for VAP has not been evaluated for children. As for adults, uncomplicated cases should be treated for 7 days. For complicated cases or those with necrotizing pneumonia, at least 14 days of therapy should be administered. Shorter courses (<7 days) may be appropriate for children with ventilator-associated tracheitis without evidence of pneumonia.⁷¹⁶

Comprehensive guidelines for prevention of health care–associated pneumonia⁷⁰⁷ and VAP¹⁴¹ are available and were updated in 2014.³⁶⁵ Key strategies include three major themes: reducing aspiration of secretions, reducing colonization of the aerodigestive tract, and preventing use of contaminated equipment.¹⁴¹ Many strategies are implemented as practice bundles that are aimed at producing more robust results when combined.^{33,63,158,535,711,718}

Strategies for prevention include limiting the duration of ventilation and using noninvasive approaches when possible. Daily assessment of readiness to wean or extubate and spontaneous breathing trials are recommended.^{141,366,729} Although a randomized clinical trial enrolling ventilated children failed to demonstrate a reduction in time to extubation with the use of a weaning protocol, most children included in the study

were weaned from ventilator support in less than 2 days.⁵⁸⁶ Minimizing sedation decreases the duration of ventilation.³⁶⁵

Aspiration can be minimized by maintaining patients in a semirecumbent position by elevating the head of the bed by 30 to 45 degrees.³⁶⁵ Head-of-bed elevation has also been associated with reductions in clinically suspected pneumonia⁷⁵⁰ and shorter ventilator stays.³⁶⁷ Keeping the endotracheal tube free of secretions is also important in preventing aspiration. Use of a cuffed endotracheal tube is recommended³⁶⁵; cuffed tubes have been proved safe in pediatric patients and are routinely used in infants and children.³⁶⁵ Suctioning should be performed by gently using a sterile, single-use catheter, and sterile fluids should be used to loosen secretions and clear the suction catheter. Other measures to reduce aspiration include avoiding unplanned extubation and reintubation and avoiding gastric overdistention.

To minimize contamination of respiratory equipment, sterile water should be used to rinse reusable devices. Tubing should be maintained in a dependent position relative to the endotracheal tube, and condensate should be routinely discarded. Circuits should remain closed during condensate removal. The ventilatory circuit should be changed only when visibly soiled or malfunctioning.³⁶⁵ All respiratory equipment should be stored and disinfected properly.¹⁴¹ Items with direct or indirect contact with mucous membranes or respiratory secretions should be cleaned thoroughly and sterilized or disinfected in a manner consistent with high-level disinfection. Hand hygiene and use of gloves during contact with objects or surfaces contaminated with respiratory secretions are also important.

Strategies to reduce colonization of the aerodigestive tract include regular oral care (e.g., toothbrushing).³⁶⁵ Oral care with antiseptics such as chlorhexidine appears to be most beneficial for cardiac surgery patients.³⁶⁵ Study results from metaanalyses of noncardiac surgery patients have shown reductions in rates of VAP for adults, but the impact on duration of ventilation, ICU length of stay, and mortality rates has not been demonstrated.^{365,389,664} One study of adults showed that daily oral care with chlorhexidine might be harmful for some patients, but this finding will require further consideration in future prevention guidelines.³⁶⁷

Prophylactic antibiotic regimens have been used to modulate oropharyngeal colonization.^{141,707} Selective decontamination of the digestive tract uses a combination of topical, nonabsorbable oral, and systemic antimicrobial agents to prevent secondary bacterial colonization and preemptively treat possible respiratory tract infection with commensal organisms.¹⁸² Selective oropharyngeal decontamination is similar but includes application of topical oropharyngeal antimicrobial agents only. Selective decontamination of the digestive tract^{173,182,379,671} has reduced mortality rates for adult ICU patients in randomized clinical trials, including a systematic review, but it is not recommended routinely because of increased selective pressure on antibiotic-resistant organisms and risk of *C. difficile* infection.^{141,366,707}

Infections Related to Instrumentation of the Urinary Tract

Catheter-associated urinary tract infections (CAUTIs) are the most common HCAs in hospitalized adults worldwide.³¹¹ In contrast, CAUTIs comprise a much smaller proportion of device-related HCAs in pediatric patients, likely due to differences in urinary tract catheterization between adults and children. However, data from the CDC's NHSN show that pooled mean rates of CAUTIs are similar for adult and pediatric ICUs.²⁰¹

Although diagnostic criteria for CAUTIs vary and are often reported differently for various studies, surveillance definitions have been established and are updated annually.^{312,573} Urinary tract infections (UTIs) are considered catheter associated if the patient had an indwelling catheter in place for more than 2 calendar days on the date of the event. Symptomatic UTIs are defined by signs or symptoms of infection (e.g., fever, urgency, frequency, dysuria, suprapubic tenderness) and a quantitative urine culture with 10^4 or more colony-forming units (CFUs) per milliliter of urine containing no more than two species.⁵⁷³

The most common organisms causing CAUTIs are those colonizing the perineum.⁶⁷⁰ Infections in patients with short-term indwelling catheters (<30 days) are usually caused by single organisms, whereas infections in patients with long-term catheters (>30 days) are more often polymicrobial.³¹¹ *E. coli* is the most commonly identified

organism.^{2,311,540} Other gram-negative bacteria (e.g., Enterobacteriaceae, *P. aeruginosa*), *Enterococcus* spp., and *Candida* spp. are also isolated.^{2,165,311,431,432,540} Receipt of antimicrobial agents increases the risk of infection with resistant bacteria or fungi. In a single-center pediatric study, antibiotic exposure within the prior 2 months was more common for children with infections with *P. aeruginosa* as compared with children with infection due to *E. coli*.⁶⁶

Microbial colonization of the urine is the first step in the pathogenesis of UTI; the urinary catheter facilitates this by perturbing host defenses and providing uropathogens easier access into the bladder. However, infection is not an inevitable result of bladder colonization, and many chronically catheterized patients have evidence of urine colonization for long periods without clinical evidence of infection. Pathogens may be introduced at catheter insertion, by ascension along the external catheter surface, or intraluminally through contamination of the collecting tube or drainage bag. A detailed culturing study of catheterized patients suggested that roughly two thirds of infections are caused by extraluminal spread of microorganisms along the external catheter surface, whereas the other one third are intraluminally acquired.⁷¹² This finding is supported by numerous studies of catheterized adults that correlated microorganisms colonizing the urethral meatus with those most frequently causing infection.⁹⁵

After catheter insertion, adherence of microbes along the internal and external surfaces of the catheter leads to colonization, facilitating the rapid formation of biofilms that migrate to the bladder within 1 to 3 days.^{311,331,626} Movement of microorganisms into the bladder is facilitated by obstruction of urine flow and reflux of urine into the bladder (i.e., raising the collection system above the level of the bladder), but many bacteria can migrate upstream even in properly maintained systems. In the bladder, microorganisms multiply in the small but persistent reservoir of urine that is incompletely drained by the catheter.⁹⁵

The reported incidence of catheter-associated bacteriuria is 3% to 8% per day; duration of catheterization is the most important risk factor.³¹¹ Other risk factors for catheter-associated bacteriuria in adults include female sex, catheter insertion outside the operating room, catheter care violations, older age, and rapidly fatal underlying illness.³¹¹

The epidemiology of bacteriuria and UTIs has been evaluated for children, although most studies are outdated.^{61,66,165,394,431,432,540} Duration of catheterization is also an important risk factor for infection in children.⁴⁰⁸ In a large, prospective study of 525 hospitalized children with urinary catheters, median duration of catheterization was 7 days (range, 2–77 days).⁴³² A retrospective analysis of CAUTIs in a tertiary care children's hospital found that more than 80% of CAUTIs were identified in critically ill children and that 75% occurred in girls. Most patients had at least one chronic underlying condition, and approximately one third had an anatomic or functional abnormality of their genitourinary tract.¹⁶⁶

The diagnosis of symptomatic CAUTIs is often challenging because many catheterized patients do not have symptoms such as urgency, frequency, or dysuria, and fever is often the most commonly identified sign. Pyuria is a reasonably good predictor of significant concentrations of gram-negative rods in the urine of catheterized patients, but it is a poor predictor of significant concentrations of enterococci or *Candida*.⁷¹³ However, pyuria alone is not diagnostic of infection in catheterized patients, particularly those with long-term indwelling catheters.³¹¹ Conversely, the absence of pyuria in a symptomatic, catheterized patient suggests an alternative diagnosis.

Definitive diagnosis of catheter-associated UTIs depends heavily on quantitative urine culture. For patients with short-term catheters, specimens should be collected from the aspiration port using aseptic technique. With long-term catheters, removing the catheter and collecting a specimen from a freshly placed catheter before initiating therapy is preferred.³¹¹ Specimens should not be collected from the drainage bag.

Empiric antimicrobial therapy for UTI should be based on the severity of clinical disease, the nature and severity of underlying conditions, and knowledge of local epidemiology. Parenteral therapy is typically used until secondary bacteremia is excluded. Therapy with a broad-spectrum agent targeting gram-negative bacilli, potentially including *P. aeruginosa*, and enterococci usually is appropriate. Antifungal therapy

can usually be withheld, unless yeast elements are identified on urinalysis or urine Gram stain. Based on the patient's clinical status and culture results, the treatment regimen can be tailored accordingly or discontinued.

Seven days of antimicrobial therapy is recommended for the treatment of most CAUTIs; longer courses (10–14 days) are used for patients with a delayed response or with evidence of pyelonephritis.³¹¹ If the infection is uncomplicated and the child has responded clinically, oral therapy can be used to complete the course. If possible, indwelling urinary catheters should be removed. Infections involving nephrostomy or suprapubic catheters often recur if the catheters must remain in place. When nephrostomy tubes must be used for extended periods, suppressive antimicrobial therapy may be considered after treatment is completed, although there is a risk for secondary infection with resistant bacteria or yeast with this approach.

Detailed guidelines for the prevention of CAUTIs have been published^{267,311} and updated in 2014.⁴²⁶ Many of these strategies have been incorporated into prevention bundles that include standardized training and catheter insertion and maintenance practices; use of a prevention bundle was associated with a significant reduction in CAUTI rates in a tertiary care children's hospital.¹⁶⁶ Additional interventions, including nurse-based or electronic physician reminder systems to reduce inappropriate catheterization, have significantly reduced the rates of CAUTI among children and adults.^{89,165,481}

Reducing unnecessary use of urinary catheters is the most important and effective preventive measure. Key prevention strategies include catheter insertion by trained personnel; attention to hand hygiene and aseptic technique during insertion; proper securement of indwelling catheters; maintenance of a sterile, continuously closed drainage system with unobstructed urine flow (i.e., keeping the collection tubing free of kinks or dependent loops); maintaining the drainage bag below the level of the bladder; and removal of the catheter as soon as possible.⁴²⁷

Although systemic antibiotics have reduced or delay the onset of catheter-associated bacteriuria or infection in adult studies,⁹⁵ their use at the time of catheter insertion, removal, or replacement is not routinely recommended owing to the potential for adverse effects and the development of antimicrobial resistance.³¹¹ Other types of interventions have been studied, primarily in adults, and most have had limited or inconsistent benefits.^{95,311,459} At Routine use of methenamine salts or cranberry products is not recommended for prevention of CAUTIs.

Infections Related to Surgical Procedures

Patients undergoing surgical procedures are at risk for a variety of HCAs, including bacteremia, pneumonia, and UTIs (often related to indwelling medical devices), but surgical site infections (SSIs) are the most common.^{59,566} Voluntary reporting of postoperative complications to the American College of Surgeons' National Surgical Quality Improvement Project (NSQIP) has generated specialty-specific data on the incidence of SSIs among children (Table 244.2).⁹¹ SSIs have a significant impact on patient outcomes, including increased duration of hospitalization, health care costs, and increased risk of death.²⁰

Consensus criteria for SSIs are available from the CDC's NHSN.¹⁰ SSIs are further categorized as incisional infections (superficial or deep) or as organ or space infections (<http://www.cdc.gov/nhsn/PDFs/pscManual/9pscSSIcurrent.pdf?agree=yes&next=Accept>). Surveillance definitions require that infections arise within 30 days of surgery, unless an implant or homograft is left in place, in which case the infection surveillance period should be extended to 90 days. Surveillance definitions require reporting of an SSI that develops after a procedure in which infection was identified (e.g., drainage of an intraabdominal infection), although these cases should be flagged as having infection at the time of surgery. Stitch abscesses are not considered SSIs.

Traditionally, the NHSN has provided simple risk adjustment measures to account for differences in case mix and allow for meaningful comparisons between surgeons or hospitals. Three equally weighted factors were previously included: composite measure of severity of illness (i.e., American Society of Anesthesiology [ASA] score); wound classification of I to IV (i.e., clean, clean-contaminated, contaminated, and dirty-infected); and procedure duration.¹⁵⁵ The NHSN developed

TABLE 244.2 Rates of Surgical Site Infections for Pediatric Surgical Specialties, American College of Surgeons National Surgical Quality Improvement Program, 2010

Specialty	SURGICAL SITE INFECTION RATES (%) ^A	
	All Cases	Neonates
Neurosurgery	6.3	12.6
General surgery	3.8	6.2
Plastic surgery	3.1	0
Orthopedics	2.5	2.7
Otolaryngology	1.1	0
Urology	1.5	2.4

^ARates have been risk adjusted using NSQIP hierarchical model.

Modified from Bruny JL, Hall BL, Barnhart DC, et al. American College of Surgeons National Surgical Quality Improvement Program Pediatric: A beta phase report.

J Pediatr Surg. 2013;48:74–80.

procedure-specific risk models for each procedure category reported to the NHSN that incorporate existing patient- and hospital-specific data elements. These models have improved predictive performance compared with traditional risk stratification and are intended to facilitate improved external benchmarking.⁵⁰⁵

In pediatric studies, independent risk factors for infection include those related to procedures, such as longer surgery duration,^{59,164,167,194} prolonged preoperative hospitalization,^{164,167,194} emergency surgery,^{58,194,730} longer length of incision,^{164,194} and procedures performed by trainees.⁷³⁰ Patient-related factors that are associated with an increased risk of SSIs include younger age or prematurity,^{92,451,659} nonwhite race,⁹² obesity, and underlying diseases, including genetic conditions.^{58,345,450,493} Potentially modifiable risk factors identified in a 2011 study included postoperative ICU admission, urinary catheter placement, and use of an implantable device.⁹²

Additional data exist for specific surgery types. Children undergoing cardiovascular surgery are at high risk for infection due to the complexity of congenital heart disease and the aggressive medical management required for support preoperatively and postoperatively. A prospective study of more than 300 children undergoing cardiovascular surgery found an infection rate of 7.1%; infection rates were higher among patients with delayed sternal closure^{206,434} and those with increased severity of illness (i.e., higher pediatric risk of mortality [PRISM] score).⁵⁶⁶ Subsequent studies identified prolonged duration of surgery,^{13,344,513} younger age^{13,50,344,513} (<30 days⁶⁸⁹), cyanotic heart disease,⁵⁰ undergoing more than one cardiothoracic procedure,³⁰⁹ having a preoperative medical device,⁶⁸⁹ and parenteral nutrition as independent risk factors.^{41,689} Gram-positive organisms are the most common cause of infection after cardiac surgical procedures;⁵⁰⁷ however, one case series reported that gram-negative pathogens were isolated from approximately one third of children with postoperative mediastinitis.⁴³⁴

Reported rates of infection after cerebrospinal fluid shunting procedures vary widely.^{393,532} Approximately 10% of newly placed shunts become infected within 1 year of placement.⁶⁷³ Risk factors for initial shunt infections include prior neurosurgical procedure, age between 6 and 12 months, and presence of a gastrostomy tube. Additional risk factors include prematurity, perioperative cerebrospinal fluid leak, surgical revisions and replacement of cerebrospinal fluid shunts, and myelomeningocele.^{337,380,532,601,673,674,676,692} Skin organisms, including *S. epidermidis* and *S. aureus*, are the most common causes of shunt infections. Adolescents have an increased incidence of shunt infections due to *Propionibacterium* spp., which can be difficult to diagnose.⁴

SSIs are common in orthopedic patients, particularly after spinal fusion. The risk of SSI is markedly elevated for children with underlying neurologic or neuromuscular conditions. The rate of infection after spinal fusion for idiopathic scoliosis is 0.5% to 1.6%, but the rate of infection for children with underlying conditions can exceed 20%.⁴⁵⁰

Factors such as bowel incontinence, malnutrition, and instrumentation that extends to the pelvis are thought to contribute to this marked difference in risk of infection. Other risk factors for infection include an ASA score greater than 2, obesity, and antibiotic prophylaxis with clindamycin were independent risk factors for infection.⁴¹⁹ Gram-positive organisms are the predominant cause of postoperative infections in children with idiopathic scoliosis, whereas gram-negative organisms are more common in children who have undergone repair of nonidiopathic scoliosis.^{450,630}

The pathogenesis of SSIs involves complex relationships of microbial characteristics, host factors, and the nature of the surgical procedure. Intraoperative contamination of the wound is presumed to be the most common mechanism of SSI. Even with careful skin preparation and expert technique, microbial contamination is virtually universal. Although skin organisms are a common cause of infection, a significant number of these organisms reside in skin appendages, such as sebaceous glands and hair follicles, which may not be eradicated by topical antiseptics.⁴⁶² Careful surgical technique is required to minimize contamination and avoid conditions that favor microbial growth postoperatively. Conditions include damaged or devascularized tissue resulting from rough handling or overuse of electrocautery and hematomas and seromas, which provide optimal bacterial growth conditions. Postoperative factors also contribute to the risk of SSI, although their relative importance remains unclear.⁴⁶³

SSIs rarely occur within 48 hours of surgery, except in cases of infection with *S. pyogenes* or *Clostridium* spp.; fever within 48 hours of surgery is unlikely to be related to the surgical site.⁶⁹⁹ Management of SSIs may require a combination of surgical debridement and antimicrobial therapy, depending on the location and extent of infection. Superficial incisional infections may be treated topically or with oral antibiotics alone, whereas deep incisional and organ or space infections typically require debridement and drainage in addition to antimicrobial therapy. If fluid collections are inaccessible or attempts at drainage may compromise the patient's condition, antibiotics may be tried alone, although the clinical response must be closely monitored.

The presence of prosthetic or foreign material increases risk of infection and complicates infection management. In particular, shunt infections are unlikely to resolve without shunt removal.⁷⁸² In some special cases, antimicrobial therapy can successfully suppress infection with foreign material while postoperative healing takes place (e.g., plates and screws to stabilize bones after orthopedic procedures). However, device removal is typically recommended to achieve cure. The likelihood of salvage of an infected prosthesis improves if the infection is detected within 3 weeks of implantation, the implant remains stable and the surrounding tissue is healthy, and the patient receives appropriate systemic antimicrobial therapy.⁷⁸⁸ With prosthetic joint infections, most patients require a minimum of 6 to 8 weeks of antimicrobial therapy.⁷⁸⁸

Evidence-based and best-practice guidelines for the prevention of SSIs are largely based on adult studies but have been generally applied to the prevention of pediatric surgical infections.^{12,84,462} Multicenter learning collaboratives and use of bundles of prevention practices have been associated with reductions in rates of surgical sites infections.^{615,732} Preoperative measures are designed to reduce the nature and degree of microbial contamination and include appropriate hair removal, hand antisepsis by surgical staff, and preoperative skin disinfection. The impact of preoperative antiseptic baths or showers on infection rates remains controversial, although this practice has been adopted by many institutions,^{12,462,758} and the practice has reduced the number of bacteria colonizing the skin.^{12,462} More substantial reduction of bacteria is seen with multiple showers or with showers immediately preceding surgery, suggesting that timing may be important.¹² Similarly, preoperative use of chlorhexidine shampoo was found to be superior to iodophor products in reducing the number of scalp microorganisms before neurosurgical procedures in children.⁴⁰³

Many adult studies have demonstrated that the preoperative use of topical antimicrobials in patients known to be colonized with *S. aureus* was associated with a reduced risk of SSIs.^{69,130,558} A meta-analysis evaluated the effect of intranasal mupirocin used alone or as a component of a prevention bundle and found it was associated with reduced rates of *S. aureus* infections in surgical patients (i.e., patients with or without documented nasal carriage of *S. aureus*).⁶⁴⁹ Mupirocin resistance was

infrequently reported in the studies included in the meta-analysis, but it has been reported after widespread use of nasal mupirocin in other studies.⁴⁸⁹

Screening of all surgical patients for colonization is costly and not recommended as a routine practice,²³ but targeted or universal decolonization may be considered for high-risk groups, such as those undergoing placement of prosthetic devices, if the rate of SSIs remains elevated despite full implementation of routine prevention bundles.

Although removing hair appears to provide a cleaner operative site, current evidence suggests that shaving is associated with higher rates of infection, presumably due to microscopic skin trauma and liberation of resident skin flora from deep skin structures.¹² If hair removal is necessary, evidence suggests that clippers should be used instead of razors.⁷¹⁹ If required, most recommend hair removal is done immediately before surgery, but a meta-analysis found no difference in infection rates between hair removal 1 day before or the day of surgery.⁷¹⁹ However, the studies were small, and authors of the meta-analysis suggested that more research is needed.

Appropriate perioperative use of antimicrobial prophylaxis is an important measure to prevent infection.⁸³ The American College of Surgeons recommends prophylactic antimicrobial agents be used if an implant is placed, there is a high risk of infection (e.g., after clean-contaminated or contaminated procedures), or the consequences of a postoperative infection are likely to be severe.

A comprehensive meta-analysis of metaanalyses included 250 clinical trials with more than 4800 patients to determine whether antibiotic prophylaxis could be effective in preventing SSIs across a variety of procedures and found that perioperative antibiotics significantly reduced infection risk across the 23 types of surgery evaluated.⁷⁶ The protective effect was sustained across different levels of surgical cleanliness.⁷⁶ A 2014 study of children undergoing general, cardiac, and spinal surgery found that risk of SSI was 70% greater for patients who did not receive appropriate perioperative antimicrobial prophylaxis.⁶⁵⁸

Guidelines for procedure-specific antimicrobial agents were updated in 2013 by The American Academy of Pediatrics' Committee on Infectious Diseases and the American Society of Health System Pharmacists.⁸³ The most effective time for antibiotic administration is within 60 minutes of skin incision, except for agents such as vancomycin that require longer infusion times and therefore should be administered 1 to 2 hours before surgery. If surgery is prolonged, repeat dosing should be performed after two half-lives of the administered agent have elapsed. Because prolonged postoperative use does not reduce the risk of infection but does increase the risk of infections due to resistant organisms, antimicrobial agents should be stopped within 24 hours after the procedure.^{160,463}

A variety of intraoperative practices and procedures are used to prevent contamination of the surgical site. Appropriate surgical hand antisepsis by surgical personnel reduces the number of bacteria on the hands and the potential for contamination through visible or microscopic breaks in surgical gloves. A systematic review found that use of an alcohol rub was as effective as aqueous scrubbing.⁷¹⁹ Skin antisepsis also reduces the number of viable bacteria at the surgical site. Evidence from randomized clinical trials and metaanalyses suggests that use of chlorhexidine is superior to that of iodophors in preventing SSIs and results in cost savings.^{162,405} Operating room traffic should be minimized because activity increases bacterial counts in the air, but the effect on infection risk is likely small. Bacterial counts can also be minimized by regularly servicing operating room ventilation systems and maintaining adequate ventilation parameters.¹⁷

Proper surgical technique is critical in preventing infection.¹² Closed-suction drainage systems are frequently used in orthopedic operations to drain fluids from the surgical wound and reduce occurrence of hematoma, although recent systematic reviews and metaanalyses have been unable to demonstrate that this practice is associated with a reduced risk of postoperative infection.^{550,753,785} Several studies have demonstrated that confidential feedback of surgeon-specific rates of infection to individual surgeons allows them to adjust their practices accordingly and reduces overall infection rates.^{23,725}

Other infection-prevention interventions recommended for adult surgical patients include maintaining glycemic control and normothermia

and use of supplemental oxygen to prevent tissue hypoxia.²³ Few data are available to determine the impact of these measures in pediatric surgical patients. Tight glycemic control may have untoward consequences in special populations of children, particularly infants. A multicenter trial of tight glycemic control in pediatric cardiac surgery patients is in progress.²³⁷

HEALTH CARE–ASSOCIATED INFECTIONS CAUSED BY SPECIAL PATHOGENS

Methicillin-Resistant *Staphylococcus Aureus*

MRSA has long been recognized as a nosocomial pathogen and accounted for more than 50% of *S. aureus* HCAs in adult patients reported to the CDC in the 1990s.⁵¹⁴ In contrast, point prevalence surveys performed in the late 1990s by the Pediatric Prevention Network documented that only 2% of pediatric HCAs were caused by MRSA.^{271,689}

The epidemiology of health care–associated MRSA has changed dramatically over the past decade. Recent data suggest that approximately one third of all *S. aureus* device-related infections in neonatal ICUs are caused by methicillin-resistant strains.³⁰⁶ Similarly, a nationwide study estimated that approximately one-third of nonneonatal hospital-onset *S. aureus* bacteremia resulted from methicillin-resistant strains.³⁶⁴

The molecular epidemiology of health care–associated MRSA infections has also changed over the past decade. In many institutions, community-associated MRSA strains, which are defined by the presence of the SCCmecIV cassette, a unique mobile genetic element, have become endemic.^{343,466} Studies of the transmission dynamics of MRSA in the health care setting suggest that colonization pressure higher than 10% is associated with a marked increase in the risk of MRSA transmission to critically ill children. The risks of in-hospital transmission are similar for health care–associated and community-associated strains of MRSA.⁵⁷⁰

The changing epidemiology of health care–associated MRSA infections has had an unfortunate impact on patients. Compared with patients with HCAs due to methicillin-sensitive strains of *S. aureus*, patients with similar infections due to MRSA often have worse outcomes with increased rates of death, longer durations of hospitalization, and higher total hospital costs.^{146,147,213,364} Risk factors for MRSA HCAs include exposure to broad-spectrum antibiotics, prolonged hospital stay, and use of indwelling medical devices.

Prevention of health care–associated MRSA infections has been the topic of several guidelines from experts in the fields of infectious diseases and hospital epidemiology.^{23,328,511,667} Recommended practices for all acute care facilities include strict adherence to hand hygiene, use of contact precautions for patients with MRSA infection or colonization, rigorous decontamination of the patient care environment and medical equipment, antimicrobial stewardship, and active surveillance for health care–associated MRSA infections.⁹⁹

For settings in which MRSA transmission persists despite full implementation of the described interventions, experts recommend active surveillance for MRSA colonization among patients who are recognized to be at high-risk or newly admitted.⁹⁹ When coupled with the use of contact precautions for MRSA-positive patients, this strategy enhances recognition and control of previously silent reservoirs. Data from a study performed in a tertiary care neonatal ICU suggested that active surveillance and cohorting might not be sufficient to prevent MRSA infections in hospitalized neonates, who may have MRSA infection before colonization can be recognized.⁵⁶⁹

Decolonization has been demonstrated in multiple studies to reduce MRSA transmission in settings where there is a high level of endemic transmission or an outbreak, including when a colonized health care worker was epidemiologically linked to MRSA transmission. A large, cluster-randomized, multicenter trial compared the impact of various control strategies on rates of MRSA infections in adult ICU patients. Investigators found that universal decolonization with intranasal mupirocin and daily chlorhexidine baths reduced the risk of MRSA infection and bloodstream infections compared with MRSA screening and isolation or MRSA screening, isolation, and targeted decolonization of patients found to be colonized with MRSA.³²⁰ However, cost-effectiveness analyses of these strategies have yielded conflicting results.^{259,319,479} In many neonatal ICUs, MRSA and methicillin-sensitive

S. aureus infections are common causes of health care–associated infections. A published observational study suggested that active surveillance for *S. aureus* and decolonization prevented *S. aureus* infections. In this study, decolonization was attempted by twice-daily application of intranasal mupirocin and two baths with 2% chlorhexidine for infants older than 36 weeks' gestational age or more than 4 weeks or daily bathing for 5 days for infants older than 2 months of age.⁵⁷¹

Although decolonization therapy can reduce the transmission of MRSA in the health care setting, multiple studies have demonstrated that a large proportion of patients and health care workers who undergo decolonization become recolonized.¹⁹² Factors that have been associated with failure to eradicate MRSA carriage include wounds, eczema, indwelling medical devices, and mupirocin-resistant MRSA.^{292,677}

Universal use of contact precautions (i.e., use of gown and gloves for all patient contacts regardless of whether a patient is known to be colonized or infected with a resistant organism) can reduce the frequency of ICU health care worker clothing contamination.⁷⁷² However, the economic costs and burdens of this approach argue against its use except in response to an outbreak.

Vancomycin-Resistant Enterococci

In contrast to methicillin-resistant strains of *S. aureus*, people with VRE colonization or infection typically have an identifiable exposure to a high-risk health care setting, a medical device, or procedure. Vancomycin resistance in *Enterococcus faecium* or *Enterococcus faecalis* arises most frequently from acquisition of a mobile genetic element that carries with it the *vanA* or *vanB* resistance gene. Although exposure to vancomycin provides selection pressure that facilitates the expansion of VRE in a colonized host, it does not induce a vancomycin-sensitive strain of *Enterococcus* to become resistant. However, antibiotic exposure has been repeatedly associated with an increased risk of colonization and infection with VRE. In a previously uncolonized patient, antibiotic use reduces populations of commensal flora, thereby lessening colonization resistance and enhancing the capacity of VRE to establish colonization in a patient who is exposed to VRE. In a patient who is already colonized with VRE, antibiotic exposure reduces the density of colonization of other flora and allows expansion of the organism.⁵¹¹ In hospitalized children, vancomycin exposure and mechanical ventilation immunosuppression, and older age were independently associated with bacteremia due to VRE, compared with vancomycin-sensitive *Enterococcus*.²⁷⁹

Three major sources are important in the transmission of VRE to patients: health care workers' hands, shared patient equipment, and the health care environment. Several observations support the importance of contaminated health care workers' hands in the transmission of VRE. First, VRE can easily be recovered from the hands and gloves of caregivers of VRE-positive patients.⁵²⁴ Second, VRE has been recovered from computer keyboards used exclusively by health care workers, indicating that hand carriage of VRE can spread the organism beyond the environment of a colonized patient.³⁰⁷ Third, having a health care worker who is simultaneously providing care to a VRE-positive and a VRE-negative patient has been demonstrated to be a risk factor for VRE acquisition.⁷⁹

Many studies have demonstrated that VRE can persist on inanimate objects and the patient care environment for long periods.⁵¹⁵ Transmission can occur when a patient comes into contact with inadequately decontaminated shared patient equipment (e.g., pulse oximeters, rectal thermometers) or is admitted to an inadequately cleaned hospital room that previously housed a VRE-positive patient.^{78,197}

Prevention of transmission of VRE relies on many of the same principles used to prevent transmission of other multidrug-resistant organisms in the health care setting. Similar to preventing MRSA transmission, strategies for interrupting patient-to-patient transmission of VRE rely on interrupting indirect transmission of the organism by health care workers' hands, shared patient equipment, or the health care environment.

As described in HICPAC's "Management of Multidrug-Resistant Organisms in Healthcare Settings, 2006,"⁶⁶⁷ a comprehensive approach to the control of epidemiologically important organisms, including VRE, should include active surveillance for infection, application of standard and transmission-based isolation precautions, disinfection of

the patient care environment, and judicious use of antibiotics.⁶⁶⁷ Several studies have demonstrated that health care workers' hands or gloves are frequently contaminated after providing care for a VRE-colonized patient.^{71,723} VRE can contaminate health care workers' hands even if gloves have been worn (presumably by unrecognized inoculation of the hand during the process of glove removal)⁷²³ or if the environment or equipment of a VRE-colonized patient was touched.⁷¹ Transmission-based precautions to prevent patient-to-patient spread of VRE also can reduce the prevalence of VRE among hospitalized patients.^{542,704}

Antibiotic exposure does not induce resistance to vancomycin but has been associated with an increased risk for colonization or infection with VRE. It remains unclear whether alterations in the agents or duration of antibiotic therapy can reduce the prevalence of VRE. However, most experts agree that limiting the spectrum and duration of antibiotic therapy to that which is required based on the known or suspected pathogens can have a beneficial impact on the spread of many multidrug-resistant organisms by lessening of selection pressure.⁶⁶⁷

Multidrug-Resistant Gram-Negative Bacilli

Multidrug-resistant gram-negative bacilli (MDR-GNB) have emerged as an important and increasingly frequent cause of HCAs. Data reported to the NHSN in 2014 revealed that 18% of HCAs due to *Enterobacteriaceae* spp. were caused by extended-spectrum β -lactamase strains and that 16% of *Pseudomonas aeruginosa* isolates were multidrug resistant.⁷⁵⁹ Although most isolates included in this report came from adult institutions, pediatric HCAs due to extended-spectrum β -lactamase (ESBL)–producing *E. coli* and *Klebsiella* spp., multidrug-resistant *Acinetobacter baumannii* and *P. aeruginosa*, and carbapenemase-producing *Enterobacteriaceae* are rapidly emerging.⁴⁴¹

In the United States, outbreaks of MDR-GNB have been reported in neonatal ICUs,⁷¹⁵ pediatric long-term care facilities,⁷⁴⁷ and cystic fibrosis centers.¹³¹ In a study of a nationwide sample of more than 368,000 pediatric samples collected from 1999 to 2012, demonstrated increases in the prevalence of *Klebsiella* spp. and *E. coli* with extended-spectrum β -lactamases in virtually all pediatric populations, including young children and outpatients, with an overall prevalence approaching 4%.⁴²⁸

Carbapenem-resistant *Enterobacteriaceae* have also emerged as a threat to children. Longitudinal analysis of pediatric isolates submitted from 1999 to 2012 to a national databank revealed that the overall prevalence of these organisms remained low at 0.08% of studied isolates. However, carbapenem resistance was most common in *Enterobacter* spp. isolates from blood cultures and patients who were 1 to 5 years of age or critically ill.⁴³⁰

Similar to other epidemiologically important drug-resistant pathogens (e.g., MRSA, VRE), MDR-GNB have frequently been isolated from the environment and equipment surrounding a colonized or infected patient. Although fewer studies have examined risk factors for endemic transmission or infection with MDR-GNB than for MRSA and VRE, outbreak investigations have frequently implicated contaminated respiratory therapy equipment (including mechanical ventilators), inappropriate use of multiuse vials of medications or diluents and urinary catheters, and inadequately cleaned patient environments as reservoirs of these organisms.⁵⁵⁷ Additional studies have implicated exposure to broad-spectrum antibiotics and underlying gastrointestinal, neurologic, or renal disease, with an increased risk of ESBL-producing GNB in pediatric populations.^{429,441,589,735,763}

The same prevention and control measures used to limit transmission of resistant gram-positive organisms in health care settings are presumed to be effective in preventing HCAs due to MDR-GNB.⁶⁶⁷ Studies have demonstrated that these organisms are often disseminated by health care workers' gloves, gowns, and hands after glove removal.⁵⁰¹ Hand hygiene remains the cornerstone of practices to prevent the transmission of MDR-GNB from patient to patient. Additional measures include identifying and controlling the reservoir of these organisms, typically through the use of standard and contact precautions, effective cleaning and disinfection of the shared patient equipment and the health care environment, and antimicrobial stewardship. Because relatively few pediatric hospitals routinely perform surveillance cultures for MDR-GNB, most infection prevention programs continue to rely on clinical cultures

to identify patients who carry a resistant gram-negative organism. The duration of carriage of these organisms is not known but is presumed to be prolonged, and contact precautions are typically continued for patients with MDR-GNB at least until the time of hospital discharge.⁴⁶⁴

Clostridium Difficile

Although toxin-producing *C. difficile* is a well-recognized cause of antimicrobial-associated diarrhea in adults, the pediatric burden has been previously underappreciated. A prospective study of health care–associated diarrhea in hospitalized children and adolescents found that as a group, viral causes were most common; however, *C. difficile*–associated diarrhea was the most common single cause and was more common in older children.³⁹⁵ Population-based and multicenter studies document a marked increase in pediatric hospitalizations associated with *C. difficile* infection.^{356,360,528,787} Data from 2011 estimate that the national burden of health care–associated *C. difficile* infection among children 1 to 17 years of age is approximately 6.3 cases per 100,000 people. The prevalence of asymptomatic carriage of toxigenic strains of *C. difficile* is very high among infants, particularly those who are hospitalized, and colonization rates can exceed 40%.^{138,412}

Because *C. difficile* is seldom found in the stool of healthy women and clusters of colonized infants can often be detected in nurseries,¹³⁸ health care–associated transmission instead of vertical transmission is the presumed mode by which neonates acquire this microorganism. Rates of colonization fall during the first 24 months of life. By 3 years of age, approximately 1% to 3% of young children are colonized with toxigenic *C. difficile*, a rate similar to that observed among asymptomatic adult populations.^{334,607,663}

An epidemic strain of *C. difficile* (i.e., NAP-1) emerged and disseminated in Canada and the United States during the mid-2000s and involved patients in the community and health care facilities.^{435,476} This strain caused severe disease in populations thought to be at low risk, including peripartum women and children.¹¹¹ Several studies suggest that the prevalence of NAP-1 strains among children with *C. difficile* infection is 20% to 30%.^{595,731} However, a single-center study of *C. difficile* isolates from children in 2013 found the prevalence of NAP-1 strains to be less than 1%.³⁶⁸ These disparate findings suggest there may be substantial geographic variation in the prevalence of this hypervirulent strain.

Risk factors for health care-associated *C. difficile* infection in children are similar to those identified for adults. Disease usually is associated with recent antimicrobial therapy. Virtually every class of antibiotics has been implicated, although at least one study implicated fluoroquinolones in particular.⁶³⁴ Another study found that exposure to three or more classes of antibiotics was the only independent risk factor for severe disease in a cohort of hospitalized children.³⁵⁹ Patients with comorbid conditions such as malignancy, solid organ transplantation, and inflammatory bowel disease have an increased risk of disease.^{360,528,548,634,708,726} An indwelling gastrostomy or jejunostomy feeding tube also is an independent risk factor for disease in children.⁶³⁴ Two adult studies have explored the relationship of humoral immunity and *C. difficile*–associated diarrhea and found that patients who had serum antibodies against *C. difficile* toxin A were less likely to develop disease when colonized or to develop recurrent disease.³⁸⁸ The implications of these findings on the epidemiology of this disease for children remain unknown.

C. difficile can be found on the hands of personnel and in the patient's immediate environment.²⁵⁶ Direct or indirect contact is responsible for the spread of this microorganism from patient to patient. Barriers (i.e., gowns and gloves) and hand hygiene reduce transmission. Vigorous environmental cleaning is important because *C. difficile* spores can heavily contaminate the environment and survive for long periods. Conventional cleaning agents may not be sporicidal, and some authorities recommend use of dilute bleach to disinfect rooms of patients with *C. difficile* infection, particularly while they have diarrhea.²⁵⁶

Emerging and Reemerging Pathogens

A variety of unusual, potentially fatal infections may be transmitted in health care settings. International air travel has increased the mobility

of the world's population, making it possible for people to travel long distances during the incubation period of infections acquired in remote settings.⁶⁵¹ A high index of suspicion for these infections and prompt institution of appropriate isolation precautions are necessary to reduce the risk for health care–associated transmission.

The West African Ebola epidemic of 2014 and 2015 is a sobering example of the dramatic risks that a community-based outbreak can pose to a health care system. Ebola is a hemorrhagic fever caused by a flavivirus, and it can be transmitted person to person through blood and body fluid exposures. The characteristic clinical course, which culminates in marked diarrhea and bleeding from mucous membranes, puts health care workers at high risk of exposure. This risk is compounded by the small inoculum required to establish infection. As was evident in the West African outbreak, shortages of trained personnel and protective equipment can lead to extensive transmission in health care settings, with many patients and health care workers becoming infected.^{72,722}

Due to international travel, countries throughout the globe had to use strict screening protocols to identify individuals who might have had early or subclinical Ebola infection. To respond to this risk, the CDC issued a national plan of preparedness that relied on a tiered approach with Frontline Healthcare Facilities that were capable and responsible for screening and isolating people who might have been exposed to Ebola and who were under investigation; Ebola Assessment Hospitals that could hospitalize and care for a person with suspected or confirmed Ebola for up to 5 days, during which time laboratory evaluation could be performed to confirm Ebola infection or establish an alternate diagnosis; and Ebola Treatment Centers that provided extended care for critically ill patients with confirmed Ebola for the duration of their illness.⁴⁸³ Key to all protocols used to provide care to patients with suspected or confirmed Ebola infection is to isolate the patient, limit unnecessary visitors and staff contact with the patient, and protect health care workers from exposure through the use of specialized personal protective equipment and heightened monitoring when donning and doffing this equipment.¹⁶⁸

Middle Eastern respiratory syndrome (MERS) is a viral respiratory infection caused by a novel coronavirus that emerged in Saudi Arabia in 2012.¹⁷² The origins of this virus are not fully understood, but camels appear to be a common reservoir of this virus and the presumed source in many cases of community-onset infection. Most people infected with MERS develop fever, cough, and progressive respiratory distress. The case-fatality rate of MERS infections exceeds 50%. Like other coronaviruses, MERS coronavirus is spread through contact and respiratory droplets. Analysis of hospital-based outbreaks suggests that the virus also spreads by droplet nuclei (i.e., particles <5 µm in diameter that can travel long distances on air currents).²⁹

Health care workers are at high risk for infection if they provide care to a MERS patient without using appropriate respiratory protection. An outbreak that occurred in South Korea in 2015 highlights the risk of travel-associated MERS. Delayed recognition of MERS infection in a traveler who was hospitalized with respiratory failure 9 days after he returned to South Korea from Saudi Arabia initiated a multihospital outbreak that lasted more than 2 months and infected 186 patients, 36 of whom died. The CDC recommends that all individuals with acute onset of febrile respiratory illnesses be screened for recent international travel.⁴⁹²

Plague is endemic in portions of the western United States and in other countries. Although rare, a recently reported case from Colorado demonstrates the potential for animal-to-human and human-to-human transmission of plague.⁶¹³ When caring for patients with known or suspected infection due to *Yersinia pestis*, health care workers should wear masks if the patient has signs or symptoms of pulmonary involvement.³²⁶ Tetracycline, doxycycline, sulfonamides, chloramphenicol, and perhaps fluoroquinolones can be used for prophylaxis of contacts.³²⁶

Some of the potential agents of bioterrorism are highly transmissible and can result in secondary health care–associated cases if a primary bioterrorism attack were to occur.^{28,73,179,300,326,500} Smallpox is the most feared of the potential agents of biological warfare because it can be transmitted by droplet nuclei over large distances, the case-fatality ratio is approximately 30%, there is no effective treatment, and much of the world's population is nonimmune or was immunized in the distant

past.³⁰⁰ Even a very limited number of cases of smallpox would be a global public health emergency, and detailed plans for containment would be needed. Hospitalized patients with smallpox would require airborne and contact isolation precautions, and health care workers caring for these patients must be vaccinated.^{300,705}

HEALTH CARE–ASSOCIATED INFECTIONS IN SPECIAL POPULATIONS

Neonates

Most healthy term neonates are born sterile but quickly become colonized with microorganisms derived from their mothers and the immediate environment. Predominant colonizers are coagulase-negative staphylococci on the skin and umbilicus and in the nose and α -hemolytic streptococci in the mouth. Acquisition of intestinal flora is more complex. Lactobacilli predominate in breastfed babies, whereas more adult flora composed of *Bacteroides* spp., other anaerobes, and *E. coli* colonize formula-fed babies.²⁶³ These commensals help inhibit colonization with pathogenic microorganisms. Because pathogens can spread quickly in crowded nurseries, rooming-in and early discharge reduce the risk for colonization of normal neonates.^{296,449}

The timing and nature of colonization of premature and full-term infants requiring care in neonatal ICUs is substantially different from that for healthy term infants. Colonization of these infants is substantially delayed, perhaps due to limited contact with their mothers, delayed enteral feeding, and administration of parenteral antimicrobial agents.^{257,263,542} As colonization develops, the density and diversity of strains is also different from those found in healthy term infants. During the initial weeks of life, the compositions of skin, respiratory, and gastrointestinal microbiomes from a premature infant are similar.⁵⁷⁴ Although coagulase-negative staphylococci colonize the skin, umbilicus, and nose of term and preterm infants,²⁶³ molecular typing studies have demonstrated that particular strains of coagulase-negative staphylococci can persist in neonatal ICUs over extended periods, are transmitted on the hands of caregivers, and cause bloodstream infections in some infants.^{322,445,555,687} Compared with healthy term infants, hospitalized neonates often have a larger proportion of intestinal flora composed of aerobic gram-negative bacilli, including *E. coli*, *Klebsiella* spp., *Enterobacter* spp., *P. aeruginosa*, *S. marcescens*, and *Citrobacter* spp.^{257,263}

Several investigators have prospectively collected stool samples from neonatal ICU patients and compared isolates recovered from stool with those subsequently recovered from blood during episodes of late-onset sepsis. Molecular analysis suggests that colonization of the gut with pathogenic organisms often precedes bacteremia.^{105,683}

S. aureus remains a significant pathogen in neonates; it may colonize a variety of sites, particularly the umbilicus and nose.²⁶³ In term neonates, staphylococcal skin and soft tissue infections, including superficial skin infections, mastitis, and omphalitis, are the most common types of neonatal *S. aureus* infection. Risk factors for neonatal colonization with *S. aureus* include maternal colonization, anogenital carriage, prematurity, low birth weight, and exposure to medical devices.^{340,358} Direct contact with colonized caregivers is presumed to be the predominant mode of transmission, although colonized mothers and visitors may also play an important role. Environmental contamination, with transmission of fomites by the hands of caregivers, has also been identified as a risk factor for MRSA acquisition.⁵⁷ Molecular analysis of strains isolated during clusters of MRSA infections or colonization have often demonstrated diversity in the isolated strains, suggesting multiple reservoirs leading to transmission.^{569,591}

Colonization of the skin, nose, umbilicus, or rectum precedes infection,³¹⁸ but there is poor correlation between rates of colonization and infection. When active surveillance is performed, the number of colonized infants typically far exceeds the number of infected infants; conversely, outbreaks of staphylococcal infection can occur in nurseries with low colonization rates. For this reason and because of cost considerations, surveillance cultures to detect colonized infants are not routinely recommended except under outbreak conditions.

MRSA has been a sporadic but recurrent problem in many neonatal ICUs for many years. However, infants in neonatal ICUs and otherwise healthy neonates are being affected by broader trends in the incidence

of MRSA infection (see [Health Care–Associated Infections Caused by Special Pathogens](#)). Data from the CDC demonstrated that approximately one-fourth of all *S. aureus* infections in hospitalized neonates were attributable to MRSA.⁴¹⁰ Risk factors for these infections include cesarean delivery (likely due to the longer postnatal hospital stay), male sex, surgical procedures, improper infection control practices associated with circumcision, and contact with an infected health care worker.^{56,519,591} Control of MRSA outbreaks includes emphasis on standard infection control practices, such as hand hygiene, use of isolation precautions, environmental disinfection, and proper disinfection/sterilization of patient care equipment.

A report demonstrated the capacity of whole-genome sequencing to aid in the identification and management of an outbreak of MRSA in a neonatal ICU.³⁷² Screening for colonization during the course of an outbreak can identify asymptotically colonized individuals, but the role of routine screening of infants and of health care workers is less clear.^{253,569}

Decolonization of colonized or infected infants may be effective in reducing the risk of invasive infection with methicillin-sensitive *S. aureus* or MRSA.⁵⁷¹ The most common decolonization regimens include chlorhexidine gluconate baths and intranasal mupirocin. Although chlorhexidine is not formally approved for use in infants less than 2 months of age, it has been adopted by many neonatal ICUs. A 2014 survey revealed that 86% of responding academic neonatal ICUs used chlorhexidine.³⁴¹ The most common indications for use included skin antisepsis at the time of dressing change and catheter insertion. One report described a reduction in neonatal CLABSI associated with adoption of regular bathing of neonates with central lines with 2% chlorhexidine gluconate.^{578,714} Several studies have examined the safety of chlorhexidine in neonates and found negligible absorption after bathing or cord care and no recognized toxicity.¹²⁷ Nonetheless, the paucity of high-quality, large studies demonstrating long-term safety of this agent have limited universal adoption.

Safety concerns are associated with other antiseptic agents that have been used on neonates. Iodophors may cause adsorption of iodine, and alcohols may cause chemical burns. These agents are not appropriate to use for bathing. A variety of antiseptic agents have been used for cord care, including triple dye (i.e., aqueous mixture of brilliant green, proflavine hemisulfate, and crystal violet), alcohol, bacitracin, chlorhexidine, and mupirocin, although extensive efficacy and safety data are not available for any of these compounds.²⁶⁵

Between 50% and 75% of women with group B streptococcal vaginal colonization transmit this microorganism to their neonates in the absence of chemoprophylaxis, although only 1% to 2% of colonized infants become infected. Although somewhat controversial, the CDC defines these and other infections transmitted from the birth canal as nosocomial infections.^{247,250} However, the impact of conventional infection control interventions on early-onset (i.e., within the first 7 days of life) invasive group B streptococcal infection is limited. Intrapartum prophylaxis of women is a far more effective intervention to reduce infection rates in neonates.^{107,646} Group B streptococci can be associated with late-onset infections (i.e., after 7 days of life) that are considered HCAs in hospitalized neonates. Outbreaks of group B streptococcal infection due to indirect contact transmission in nurseries have been well documented.^{204,264,525}

Preterm infants are particularly susceptible to infection caused by a variety of yeasts and, to a lesser extent, filamentous fungi; *Candida* spp. are the most common fungal pathogens that infect hospitalized neonates.²⁷ Infants likely become colonized on their skin and gastrointestinal tracts due to carriage of *Candida*, which can then predispose to invasive infection.^{546,551,608} Risk factors for colonization or infection with *Candida* include treatment with H₂-blockers, broad-spectrum antibiotics, age older than 7 days, vaginal birth, and delayed enteral feeding.⁶²² Risk factors for bloodstream infection and the use of prophylactic fluconazole have been discussed previously (see [Infections Related to Intravascular Catheters and Infusions](#)). Risk factors for *Malassezia furfur* infection are similar to those for *Candida*, but the association with lipid emulsion is particularly strong because this organism is obligatorily lipophilic.^{161,433,597} Infections caused by filamentous fungi are rare and are usually associated with contaminated devices or practices that facilitate cutaneous invasion.^{496,608}

Citrobacter koseri (previously classified as *C. diversus*) has been responsible for a number of outbreaks of HCAs among neonates.^{418,552,771} Although most infants colonized with this microorganism do not develop clinical disease, infection typically results in meningitis due to the particular neurotropism of this bacterium. Neonatal *Citrobacter* meningitis is usually accompanied by formation of one or more brain abscesses and is associated with serious long-term neurologic sequelae. Sporadic outbreaks of *Citrobacter* infection have been reported,^{418,552,771} and several published outbreak investigations have implicated transmission of this bacterium from the hands of caregivers to neonatal patients.^{552,771} Molecular techniques have demonstrated that *C. koseri* also can be acquired perinatally by vertical transmission.²⁹⁵

Enterobacter sakazakii is a rare cause of HCAI in neonates.⁷⁰¹ Similar to infections caused by *C. koseri*, infections caused by this bacterium are usually severe, often involving meningitis and brain abscess.^{62,110,137,391,672,739} Outbreaks of *E. sakazakii* infection have implicated a variety of products,^{110,391} including intrinsically contaminated powdered milk formulas.^{62,110,512,672,739} Because powdered formulas are not marketed as sterile products, feeding practices in neonatal ICUs need to balance the relative nutritional benefits of particular products against the small but real risk of infection with *E. sakazakii* and other potential pathogens.

Newer obstetric practices, such as fetal surgery, may pose unique infectious threats to the fetus and newborn, although few cases of prenatal infection have been reported.¹⁹⁵ Water births have also been associated with infectious complications, as demonstrated by the report of a case of *Legionella* pneumonia in an infant after a prolonged delivery in a pool with contaminated water.²²⁶

Hand hygiene is the most effective intervention to prevent spread of pathogenic microorganisms.⁸⁰ However, the hands of some staff may remain colonized with these microorganisms for prolonged periods despite scrupulous hand cleansing.²⁶³ Use of artificial nails or nail wraps has been associated with carriage of *P. aeruginosa* on the hands of health care workers in a neonatal ICU.²²² Health care workers should not be allowed to wear artificial nails or nail wraps when providing hands-on patient care.⁶²¹ Alcohol-based hand rubs are the most effective agents in reducing hand colonization with pathogenic bacteria and are the preferred method for hand hygiene when hands are not visibly soiled.⁸⁰

Preceding sections contain specific recommendations for the prevention of HCAs caused by community pathogens and infections related to the use of invasive devices. Other general references regarding the prevention of infections in normal nurseries and neonatal ICUs have been published, including recommendations regarding the design of facilities, appropriate staffing, and general infection prevention procedures.^{19,139,603} Several interventions designed specifically to prevent HCAs in high-risk infants deserve additional comment.

The Vermont Oxford Network, which conducts the evidence-based quality improvement collaborative for neonatology, is a large, multicenter network of neonatal units organized for the purpose of implementing evidenced-based interventions to improve the quality of care of neonates.^{313,520} Data from a group of 669 neonatal ICUs spanning the years 2000 through 2009 describe a significant reduction in late bacterial infections. In 2000, 21.1% of surviving infants weighing 501 to 1500 g experienced a late bacterial or fungal infection, whereas the rate of late infections was 15.0% for similar infants in 2009.³¹³

Many investigators have attempted to manipulate the flora that colonize hospitalized infants in neonatal ICUs to interfere with colonization by potential pathogens.^{254,448,551} Some of the studies using viridans streptococci demonstrated favorable results, but this approach has not been pursued, in part due to concern about the potential for adverse events.^{265,351,487,593} One study examined the impact of universal glove use before all patient care and venous catheter manipulations. In a single-center study, investigators observed a reduction in the frequency of bloodstream infections due to gram-positive organisms.^{348,351} Caution has been sounded, however, to the adoption of this practice until additional data are available due to the well-recognized unintended consequences associated with glove use (e.g., lower compliance with hand hygiene, reduced episodes of hands-on patient care).¹⁴⁰

Infants of extremely low birth weight have immature, fragile skin that is predisposed to drying and cracking and may not be an adequate barrier to prevent invasion by bacteria colonizing the skin. Products

containing emollients that include fatty acids have been developed to reduce transepidermal fluid loss and improve skin barrier function in very-low-birth-weight infants. A randomized, controlled trial of the effect of an emollient ointment (Aquaphor) in infants with a birth weight of 501 to 1000 g and a gestational age of 30 weeks or less was conducted in 53 neonatal ICUs participating in the Vermont Oxford Network.¹⁹⁸ Although this intervention was associated with improved skin condition, the treatment group had a higher rate of late-onset bacterial sepsis (although there was no effect on mortality rates). In contrast, two randomized, controlled trials conducted in Bangladesh found that sunflower seed oil reduced the rate of late-onset infection and mortality rates for preterm infants with a gestational age of 33 weeks or less.^{159,161,160} The increased risk of infection that is observed among premature infants in neonatal ICUs in limited resource settings compared with the United States likely contributes to the differential impact of these interventions.

Because premature infants lack sufficient levels of opsonizing antibodies, many trials have examined the efficacy of intravenous immunoglobulin in preventing infection in premature infants,^{41,206,345,415,702} only one of which demonstrated any benefit in reducing overall infection rates.⁴¹ In contrast, a large trial that randomized almost 3500 infants with suspected or proven infection found therapy with intravenous immunoglobulin had no impact on death or major disability.⁸³ A published Cochrane review analyzed all published studies and concluded that “routine administration of intravenous immunoglobulin (IVIG) or IgM-enriched IVIG to prevent mortality in infants with suspected or proven neonatal infection is not recommended. No further research is recommended.”⁵³⁶

Because preterm infants have limited neutrophil pools and limited neutrophil function, several randomized, controlled studies have examined the prophylactic and therapeutic effect of granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) on infections in preterm infants. In all of these studies, infants receiving these agents had higher peripheral blood neutrophil counts than infants receiving placebo. However, the evidence of the beneficial effects of treatment with these agents is limited.^{94,101,457,467}

Leukocytes in stored blood products may have adverse effects on immune function, especially in preterm infants. However, a study examining the effect of a universal prestorage red blood cell leukoreduction program found no effect on bloodstream infection and mortality rates but was associated with improvements in other clinical outcomes.²¹⁰ Use of postnatal corticosteroids to prevent or treat chronic lung disease in preterm infants has been associated with higher rates of HCAs⁶⁴⁰ and other short-term and long-term adverse outcomes.¹⁴¹

Immunocompromised Children

Children with congenital or acquired immunocompromising conditions are at high risk for HCAs. The risk for these infections is related to host factors, such as the nature and severity of immunocompromise, use of indwelling medical devices, and frequency and nature of exposure to the health care environment.

The epidemiology of and risk factors associated with HCAs in immunocompromised children have been best characterized for children with oncologic conditions. Investigators from St. Jude Children’s Research Hospital have described the epidemiology of HCAs for their patients and reported that CLABSIs comprised approximately one third of all identified HCAs.⁴³⁵ A large, multicenter collaborative engaged 32 multidisciplinary teams from pediatric hematology-oncology units and demonstrated a significant reduction in CLABSIs associated with implementation of a catheter care bundle; the mean infection rate fell from 2.85 to 2.02 cases per 1000 catheter days over the 32-month program.⁹⁴ A single-center, well-controlled study determined the attributable outcomes of CLABSI in pediatric oncology patients. These investigators found that a single CLABSI was associated with a 21-day increased length of stay and almost \$70,000 increase in health care costs.⁷⁷³

Risk factors associated with CLABSIs in pediatric oncology patients include neutropenia, platelet transfusion, and recent catheter placement.^{353,475} Injury of the mucosal barriers of the oropharynx and

gastrointestinal tract pose a unique threat of bloodstream infection. A new CLABSI surveillance definition was introduced in 2013 to identify the events that may arise due to translocation of bacteria across a disrupted epithelium rather than breeches in technique during the placement or use of a catheter.⁵³⁷

The risk for HCAs in children undergoing bone marrow or solid organ transplantation can be influenced by factors related to the patient's underlying health status, microbiologic characteristics of the donor and recipient of the graft, the duration and nature of immunosuppression required for successful engraftment of the transplanted organ, and the duration and nature of exposure to medical devices and the health care setting.³⁵³ Solid organ transplant recipients are at risk for SSIs and for bacterial and fungal infections associated with the use of medical devices. Severe manifestations of common childhood viruses, particularly respiratory viruses, can also pose a threat to a child who has recently undergone organ transplantation. Visitor screening, annual influenza vaccination of health care providers and family members, and appropriate use of sick leave are thought to reduce the risk of health care–associated viral infections.^{278,706}

Immunocompromised children require the same strategies described earlier to prevent HCAs when they undergo an invasive procedure, surgery, or have a medical device. For children with nonpermanent immunocompromising conditions (e.g., those receiving chemotherapy or initiating antiretroviral therapy), all elective surgeries and invasive procedures should be deferred until their immunocompromised state has resolved.

The increased susceptibility to opportunistic pathogens necessitates heightened infection prevention measures for some children with the most profound degree of immunosuppression. Numerous outbreaks due to low-virulence organisms commonly found in the environment, such as mold infections related to construction in or near a health care facility, have been reported.⁵⁶⁴ Because airborne fungal spores can enter the health care environment, the CDC recommends that the most severely immunocompromised patients, such as neutropenic patients undergoing allogeneic stem cell transplantation, remain in a protective environment that includes added engineering measures such as a positive-pressure patient care environment, high-efficiency particulate air filtering, selective air-handling units, and high numbers of air exchanges per hour (>12/hour).⁶⁵¹

Despite the broad adoption of these recommendations by many centers that care for high-risk oncology patients in the United States, relatively few studies have demonstrated their effectiveness. A meta-analysis was unable to demonstrate that measures to control the air quality reduced the risk of invasive mold infections,⁶⁴⁵ and a systematic review described an association between high-efficiency particulate air filtration and a reduction in fungal infections only when the analysis was limited to nonrandomized studies.²⁰⁵

Children With Burns

Relatively few reports describe the epidemiology of HCAs in pediatric burn patients, and most are likely outdated.^{148,248,644,733,756} Using modified CDC definitions, investigators found infection of the burn wound occurred in 10% of patients, or an incidence density of 5.6 burn infections per 1000 patient-days.⁷⁵⁶ Data from 2013 that was submitted to the NHSN from adult and pediatric critical care burn units found the median rate of CLABSI was 2.2 cases per 1000 catheter-days.²⁰¹ Although pediatric-specific data are not available for dedicated pediatric burn units, it is reasonable to presume that the rates of rates of HCAs are similar in adult and dedicated pediatric burn centers. New definitions for burn infection were developed and endorsed by a consensus conference convened by the American Burn Association²⁶⁹ and have been incorporated into NHSN definitions.³¹²

The risk and microbiology of burn infections are related to the size of the burn wound and the time of onset of the infection. Infections in burn patients can arise from endogenous organisms (often organisms colonizing the wound) or exogenous organisms. Colonization of a burn typically proceeds from gram-positive organisms, antibiotic-susceptible gram-negative organisms, and fungal and antibiotic-resistant gram-negative organisms.⁵⁸⁴ Gram-positive cocci, including methicillin-susceptible *S. aureus* and MRSA, were the most common cause of burn infection in patients with relatively small burns (<30% of body surface

area), whereas gram-negative bacteria (especially *P. aeruginosa*) were more common causes of infection in patients with extensive burns (>30% of body surface area).

Interventions to reduce the incidence of HCAs in burn patients include the use of barrier techniques to reduce cross-colonization of patients, measures to prevent cross colonization of patients during hydrotherapy treatments, topical antibiotics to retard growth of microorganisms in the burn wound, appropriate use of systemic antibiotics, and early excision and closure of the burn wound. The Shriners Burns Hospital in Boston has been successful in controlling infections in severely burned children using these methods and bacteria-controlled nursing units (i.e., laminar airflow units providing controlled temperature and humidity combined with barrier precautions).⁷⁵⁷ A randomized, controlled trial of selective decontamination of the digestive tract using polymyxin E, tobramycin, and amphotericin B in severely burned children found no evidence of benefit.⁴³

Children With Cystic Fibrosis

In 2003, Saiman and Siegel reviewed the epidemiology of important pathogens in people with cystic fibrosis and convened an international consensus conference to develop evidence-based guidelines for standardized microbiologic and infection control practices for those with cystic fibrosis.⁶²⁴ Key elements of this guideline included the need to interrupt the transmission of *Burkholderia cepacia* complex, *P. aeruginosa*, and MRSA among individuals with cystic fibrosis in health care settings. The 2014 guideline emphasized standard infection control practices, such as appropriate hand hygiene, proper use of isolation precautions, and effective procedures for cleaning and disinfecting or sterilizing reused equipment contaminated with respiratory secretions.⁶²⁵ These updated guidelines include several novel recommendations intended to limit person-to-person transmission of pathogens that threaten the health of patients with cystic fibrosis based on the observation that they can harbor critical microorganisms (e.g., *P. aeruginosa*, *B. cepacia*) for months before detection on respiratory tract cultures. Contact precautions are recommended for use in inpatient and ambulatory settings for all patients with cystic fibrosis. Patients should be advised to avoid close contact with each other, with at least 6 feet separating them in all clinical settings. They also are advised to wear a mask at all times while they are within a facility that provides health care.

In inpatient settings, the guideline recommends contact isolation and a single-patient room for patients with cystic fibrosis, regardless of colonization status. However, patients who are not colonized with MRSA, *B. cepacia* complex, and multidrug-resistant *P. aeruginosa* may share a room with a patient who does not have cystic fibrosis and who is at low risk for infection with these bacteria if a single-patient room is not available. All patients, whether colonized with these bacteria or not, should avoid contact with other patients with cystic fibrosis. All patients should receive annual influenza vaccination and age-appropriate pneumococcal vaccination.

Children Undergoing Dialysis

Children with chronic renal failure who are undergoing hemodialysis or peritoneal dialysis have multiple risk factors for HCAs. Renal failure is associated with impaired immune function, including phagocyte dysfunction due to uremia. Children with renal failure often require frequent contacts with the health care system, including hospitalization, further increasing the risk of acquiring multidrug-resistant organisms. The indwelling medical devices required for dialysis pose additional risks. Studies of adult patients with end-stage renal disease have demonstrated an increased risk of infection associated with an immunocompromised condition related to an underlying disease process or use of immunosuppressing therapies, anemia, or iron overload.³⁸

Infection of dialysis access devices for hemodialysis or peritoneal dialysis remains the most common type of HCAI among patients with end-stage renal disease.³⁸ For hemodialysis patients, the risk for bacteremia is influenced by the type of vascular access device in use. Arteriovenous fistulas are associated with the lowest risk of bacteremia, in contrast to nontunneled dialysis catheters, for which the risk for bacteremia can approach 22.5 infections per 1000 dialysis procedures, which is 7-fold to 10-fold higher than the rate of infections reported for patients undergoing

dialysis through an arteriovenous fistula during the same period.^{308,720} Adult studies have demonstrated that comorbid conditions (particularly diabetes mellitus and hypertension) are independently associated with an increased risk of bacteremia for patients undergoing hemodialysis.⁴⁰⁹ Gram-positive organisms are the most common cause of bacteremia in patients undergoing hemodialysis; *S. aureus* and coagulase-negative staphylococci are the most frequently isolated pathogens.

Many of the same practices used to prevent catheter-associated bloodstream infections in patients with conventional central venous catheters are considered standard of care for patients with hemodialysis catheters, although there are several important differences. In contrast to exit sites for conventional venous catheters, current guidelines recommend that antiseptic or antibacterial ointment (i.e., povidone-iodine or bacitracin/gramicidin/polymyxin B) be placed at the exit site of hemodialysis catheters after insertion and after each dialysis session provided the catheter material is compatible with the substance.⁵³³

Efforts to increase the use of arteriovenous fistulas and improve the access techniques have resulted in substantial reductions in the rate of bacteremia among adult dialysis patients. For hemodialysis patients with a history of multiple episodes of bacteremia, several metaanalyses^{390,780} and a randomized trial have demonstrated that use of antibiotic or antiseptic locks between dialysis sessions were associated with a reduced risk of subsequent bacteremia.⁶⁹⁰ Although few data are available from studies of pediatric patients, application of these same strategies to pediatric patients undergoing hemodialysis is likely to reduce the risk for bacteremia in this patient population.

Peritonitis is the most common HCAI in patients undergoing intermittent or continuous peritoneal dialysis. In addition to raising the risk of infection-related death, peritonitis poses long-term risks for patients who require chronic dialysis. Repeated or protracted episodes of inflammation of the peritoneum can result in permanent fibrosis of the peritoneal membrane and render peritoneal dialysis ineffective. Pediatric data suggest gram-positive organisms account for 44% of cases of culture-positive peritonitis. Approximately half of the gram-positive isolates were *S. aureus*, and the remaining isolates were coagulase-negative staphylococci. Approximately 50% of pediatric peritonitis cases in this population are caused by gram-negative organisms, whereas less than 5% of episodes are caused by fungi.¹²⁴

Using data from the International Pediatric Peritoneal Dialysis Registry, the International Society for Peritoneal Dialysis has published guidelines for the treatment and prevention of peritonitis in pediatric patients.⁷⁵¹ They recommend that antibiotics be administered by the intraperitoneal route for the treatment of peritonitis. Empiric antibiotics should be selected based on available data on local resistance patterns of likely infecting organisms. Vancomycin is not routinely recommended for empiric therapy unless the institution's rate of MRSA exceeds 10% or the patient has a history of MRSA colonization or infection.⁷⁵¹ Definitive therapy should be tailored after the organism has been isolated and susceptibility data are available. The recommended duration of therapy is based on the infecting organism but ranges from 2 to 3 weeks for most bacterial pathogens. Replacement of the peritoneal catheter is recommended for cases of refractory or relapsing bacterial peritonitis, in the setting of a tunnel infection, and for fungal peritonitis.

Prevention of HCAIs in children undergoing peritoneal dialysis rests on the same principles used to prevent intravascular infections: scrupulous adherence to aseptic technique during catheter insertion and access and close attention to the care of the catheter exit site. A multicenter collaborative defined the most important strategies (i.e., best-care bundles) to prevent infections in pediatric patients with end-stage renal disease receiving peritoneal dialysis.⁵¹⁶ The collaborative observed an overall rate of peritonitis of 0.46 episodes per patient-year and found that the site-specific rate of peritonitis was inversely related to the degree of compliance with the peritoneal dialysis care catheter bundle.⁶⁵⁶ Consensus guidelines for the prevention and treatment of catheter-related infections and peritonitis in pediatric patients receiving peritoneal dialysis were updated in 2012.⁷⁵¹

Children in Long-Term Care Facilities

Several reports have described the burden and spectrum of HCAIs among children in long-term care facilities. A prospective, longitudinal

study of four pediatric facilities described the spectrum of endemic nosocomial infections over a 2-year period in the 1990s.⁷⁴⁶ The cumulative incidence of infection was 40%. Upper respiratory tract infections and UTIs were the most common types of infection and accounted for 37% and 31% of infections, respectively. Most UTIs occurred in a small group of patients with functional or anatomic genitourinary abnormalities related to neural tube defects or neuromuscular disorders, although the investigators did not differentiate between symptomatic infections and asymptomatic bacteriuria. A later report described the burden of device-related infections in this population.²⁹⁴ The incidence of CAUTI was more than twice as common among pediatric ICUs reporting data to the National Nosocomial Infections Surveillance System, whereas the incidences of VAP and central venous catheter–associated bloodstream infections were equivalent or slightly lower than that reported from pediatric ICUs. A single-center retrospective study performed at a 109-bed pediatric long-term care facility in 2009 reported the incidence of HCAIs to be 6.21 infections per 1000 resident-days.³ In this study, streptococcal and staphylococcal skin infections were the most commonly identified infections.

Due to limited active surveillance in many pediatric long-term care facilities, there is likely underrecognition of endemic HCAIs that occur in these settings. The residential setting and the behavioral activities of children, however, likely contribute to a significant risk of clusters or outbreaks of HCAIs due to respiratory and gastrointestinal pathogens. In a 4-year retrospective study of three pediatric long-term care facilities, investigators identified a total of 62 outbreaks that involved 700 patients.⁵¹⁰ Outbreaks due to respiratory viruses were most common and were associated with the largest numbers of confirmed cases in residents and staff. Gastroenteritis, particularly that due to norovirus, was relatively common and associated with large numbers of suspected cases. Because of the heterogeneity in the populations of patients served and the ongoing improvement efforts underway at virtually all sites where health care is provided, caution must be exercised when selecting a benchmark with which to compare a facility's rates of HCAIs.

Guidelines for the infrastructure and essential activities of infection control programs and key prevention practices in long-term care facilities have been published, although they do not specifically address issues unique to children in long-term care facilities.^{232,679,682} Key prevention measures are effective hand hygiene, appropriate use of barriers and isolation precautions, proper care of patients with indwelling devices (e.g., tracheostomies) or who require invasive procedures (e.g., bladder catheterization), prevention of decubitus ulcers, age-appropriate immunization (including yearly influenza vaccine), and early detection and control of outbreaks of infection.

Similar to reports from adult facilities, adherence to hand hygiene practices can be suboptimal. In a multicenter study, investigators observed an overall rate of hand hygiene compliance that was approximately 40% and found that compliance was much lower for nonclinical than clinical staff (14% vs. 61%).⁹³

INFECTION PREVENTION AND CONTROL PROGRAMS IN HEALTH CARE FACILITIES

This section highlights key elements of a comprehensive program to prevent and control HCAIs in health care facilities that provide inpatient care for pediatric patients. A detailed description of the development, implementation, and maintenance of an effective program is beyond the scope of this chapter, but several excellent and authoritative references on this topic are available.^{183,336,399,474,764}

Many external groups and organizations have significant influence on infection prevention and control programs in health care facilities. Their activities are outlined in Table 244.3.

Organization and Activities of Health Care Infection Control Programs

In 1998, a consensus panel of national experts published a report on the requirements for infrastructure and activities of HCAI prevention and control programs.⁶⁴¹ The specific recommendations of the panel are listed in Table 244.4, accompanied by an indication of the strength of the recommendation, and they are described in more detail in the

TABLE 244.3 External Groups and Organizations Influencing Health Care–Associated Infection Prevention and Control Programs

Group or Organization	Activities
Division of Healthcare Quality Promotion (DHQP), National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), Centers for Disease Control and Prevention (CDC)	Provides data and guidance on prevention of health care–associated infections (HCAIs); antimicrobial resistance; adverse drug events; blood, organ and tissue safety; immunization safety; and other related adverse events or medical errors in health care affecting patients and health care personnel Investigates and responds to emerging infections and related adverse events among patients and health care personnel Conducts epidemiologic and basic and applied laboratory research to identify new strategies to prevent HCAIs, antimicrobial resistance, and related adverse events or medical errors Serves as the national reference laboratory for the identification and antimicrobial susceptibility testing of pathogens that cause HCAIs
National Healthcare Safety Network (NHSN)	Collects and reports data on the incidence of HCAIs, antimicrobial use and resistance, and process measures tightly linked with prevention of HCAIs
Healthcare Infection Control Practices Advisory Committee (HICPAC)	Provides guidance to DHQP regarding surveillance, prevention, and control of HCAIs; publishes evidence-based guidelines for HCAI prevention
US Department of Health and Human Services (HHS)	Develops the National Action Plan to Prevent Health Care—Associated Infections: Roadmap to Elimination, which includes components for acute care hospitals, ambulatory surgical centers, end-stage renal disease facilities, and long-term care facilities
Center for Medicare and Medicaid Services (CMS)	Requires reporting of some HCAIs by facilities providing care to Medicare and Medicaid beneficiaries Comparative data available for public viewing on the CMS Hospital Compare website Leads the Partnership for Patients, which aims to reduce preventable harms, including HCAIs
State health departments	Require public reporting of institutional rates of HCAIs, with specifics varying by state
Professional societies: Society of Healthcare Epidemiology of America (SHEA) Association for Professionals in Infection Control and Epidemiology (APIC) Infectious Diseases Society of America (IDSA)	Advocate for public policy related to prevention of HCAIs Develop and collaborate on publication of evidence-based guidelines for HCAI prevention Provide training for health care epidemiologists and infection preventionists Sponsor scientific meetings on HCAI prevention Publish journals, including articles on HCAI prevention
The Joint Commission	Provides accreditation standards for infection prevention and control programs; promulgates National Patient Safety Goals, which includes goals related to prevention of HCAIs
National Quality Forum	Selects measures of health care quality
Occupational Safety and Health Administration (OSHA) of the US Department of Labor	Issues regulations to minimize occupational hazards to health care workers, including exposure to bloodborne pathogens and tuberculosis
Institute of Medicine (IOM)	Publishes scientific reports related to improving patient safety and reducing HCAIs
Institute for Healthcare Improvement (IHI)	Provides guidance documents on performance improvement regarding patient safety, including preventing HCAIs Conducts campaigns to improve patient safety Provides training for patient safety officers
Children’s Hospital Association	Coordinates performance improvement collaboratives to reduce HCAIs
Vermont Oxford Network	Collects and reports outcomes of neonatal care, including late-onset sepsis Coordinates improvement collaboratives to improve outcomes, including reducing late-onset sepsis
National Surgical Quality Improvement Project	Coordinates an outcomes-based program to measure and improve the quality of surgical care, including prevention of surgical site infections
Consumers Union	Publishes reports and ranking of hospitals with respect to HCAI prevention Advocates for patient safety

report.⁶⁴¹ A similar document outlining the elements of infection prevention and control in long-term care facilities has been published.⁶⁷⁹ Another guideline describes the skills and competencies of people who lead these programs.³⁵² These publications do not deal specifically with pediatric issues, although the recommendations are generally applicable to facilities providing care to children.

Surveillance Strategies

Surveillance of HCAIs is necessary to understand the specific infection problems of individual facilities, to provide a means of evaluating the effectiveness of interventions to reduce the frequency of these infections, and to facilitate detection of outbreaks of infection. Infection prevention and control programs should have a surveillance plan for the health care facility that is based on the prioritized risks associated with care provided to patients in the facility and sound epidemiologic principles.⁴⁰⁶

The CDC NHSN surveillance methodology has become the de facto standard for surveillance. Although not without limitations, the methodology is well defined and time tested and allows institutions to benchmark themselves in relation to other institutions through periodic

data summaries from the NHSN.²⁰² NHSN methodology is used extensively by states and by the CMS for public reporting of rates of HCAIs (see Table 244.3). The CDC’s NHSN has posted definitions for HCAIs with detailed instructions on the application of its methods on its website (<http://www.cdc.gov/nhsn/enrolled-facilities/index.html>).

Surveillance should examine adherence to processes that are tightly linked to outcomes. For example, facilities should monitor adherence with hand hygiene, transmission-based isolation precautions,^{85,639} and intervention bundles to prevent CLABSI, CAUTI, and SSI.^{63,490,523,577} These process measures can be used to guide and monitor improvement efforts.

Surveillance and reporting of communicable infections to state departments of health is a duty of infection prevention and control programs. It is often done in collaboration with the facility’s microbiology laboratory.

Outbreak Investigation

Because outbreaks of HCAIs are often associated with significant patient morbidity and mortality, clusters of infection should be investigated

TABLE 244.4 Consensus Panel Recommendations for the Requirements for Infrastructure and Essential Activities of Infection Control and Epidemiology in Hospitals

Recommendation	Category ^a
Critical Data and Information	
Surveillance of nosocomial infections must be performed.	I
Surveillance data must be analyzed appropriately and used to monitor and improve infection control and health care outcomes.	I
Clinical performance and assessment indicators used to support external comparative measurements should meet the criteria delineated by the Society for Healthcare Epidemiology of America (SHEA) and Association of Professionals in Infection Control and Epidemiology (APIC).	II
Policies and Procedures	
Written infection prevention and control policies and procedures must be established, implemented, and updated periodically.	II and III
Policies and procedures should be monitored periodically for performance.	II and III
Regulations, Guidelines, and Accreditation Requirements	
Health care facilities should use infection control personnel to assist in maintaining compliance with relevant regulatory and accreditation requirements.	II
Infection control personnel should have appropriate access to medical or other relevant records and to staff members who can provide information on the adequacy of the institution's compliance with regard to regulations, standards, and guidelines.	II
The infection control program should collaborate with and provide liaison to appropriate local and state health departments for reporting of communicable diseases and related conditions and to assist with the control of infectious diseases.	II and III
Employee Health	
The infection control program personnel should work collaboratively with the facility's employee health program personnel.	II
At the time of employment, all facility personnel should be evaluated by the employee health program for conditions related to communicable diseases.	II and III
Appropriate employees or other health care workers should have periodic medical evaluations to assess for new conditions related to infectious diseases that may have an impact on patient care, the employee, or other health care workers, including review of immunization and tuberculosis skin test status if appropriate.	II and III
Employees must be offered appropriate immunizations for communicable diseases.	I and III
The employee health program should develop policies and procedures for the evaluation of ill employees, including assessment of disease communicability, indications for work restrictions, and management of employees who have been exposed to infectious diseases, including postexposure prophylaxis and work restrictions.	I
Prevention of Transmission of Infectious Diseases	
All health care facilities must have the capacity to identify the occurrence of outbreaks or clusters of infectious diseases.	I
All health care facilities must have access to the services of personnel trained and experienced in conducting outbreak investigations.	II
When an outbreak occurs, the infection control team must have adequate resources and the authority to ensure a comprehensive and timely investigation and the implementation of appropriate control measures.	II
Education and Training of Health Care Workers	
Health care facilities must provide ongoing educational programs in infection prevention and control to health care workers.	II and III
Educational programs should be evaluated periodically for effectiveness, and attendance should be monitored.	II and III
Personnel	
The personnel and supporting resources, including secretarial services, available to the hospital epidemiology and infection control program should be proportional to the size, complexity, and estimated risk for the population served by the institution.	II
All hospitals should have the continuing services of trained hospital epidemiologists and infection control professionals.	I
Infection control professionals should be encouraged to obtain certification in infection control.	II
Health care facilities should provide or make available in a timely fashion sufficient office space, equipment, statistical and computer support, and clinical microbiology and pathology laboratory services to support the surveillance, prevention, and control program of the institution.	II

^aCategories: I, strongly recommended for implementation based on evidence from at least one properly randomized, controlled trial or evidence from at least one well-designed clinical trial without randomization or evidence from cohort or case-control analytic studies (preferably from more than one center) or evidence from multiple time-series studies. II, recommended for implementation based on published clinical experience or descriptive studies or reports of expert committees or opinions of respected authorities. III, recommended when required by government rules or regulations.

From Scheckler WE, Brimhall D, Buck AS, et al. Requirements for infrastructure and essential activities of infection control and epidemiology in hospitals: a consensus panel report. *Infect Control Hosp Epidemiol*. 1998;19:114–124.

promptly. A single, highly unusual infection (e.g., postoperative group A streptococcal infection) is sufficient cause for an investigation. Clusters of HCAs caused by an uncommon microorganism, a common microorganism with an unusual antimicrobial susceptibility pattern, or a series of infections at the same anatomic site (e.g., outbreak of diarrhea) also are indications for an investigation. However, some outbreaks are more difficult to recognize because they occur intermittently, involve multiple microorganisms, involve infection at various anatomic sites, or have long incubation periods.

Box 244.3 provides an outline of the steps involved in investigating a cluster of HCAs. Detailed discussions of the methods used for outbreak investigation can be found elsewhere.^{47,183,336,399,474,764} Published outbreak

investigations are an invaluable resource because they provide insight into potential causes. However, it is hazardous to jump to conclusions regarding the cause of a particular cluster of infections based on the results of a prior investigation. Careful investigation is necessary to establish or refute epidemiologic links between cases and potential causes.

Molecular genotyping techniques are an important adjunct to traditional epidemiologic methods and can serve as a powerful tool to confirm or refute a particular source or mode of transmission of a particular microorganism. Several reports have described the use of whole-genome sequencing in outbreak investigations and the insight this method provided in understanding the spread of health care–acquired pathogens.^{372,685}

BOX 244.3 Approach to the Investigation of Clusters of Health Care–Associated Infections

1. Confirm the diagnosis.
2. Make a case definition.^a
3. Search for additional cases.
4. Plot the epidemic curve.
5. Compare rates before the epidemic with current rates using statistical tests to prove that an epidemic exists.
6. Perform a literature review.
7. Open lines of communication with leaders of relevant departments, the microbiology laboratory, and the hospital administration.
8. Keep detailed records of events and conversations.
9. Review charts of all cases, and compile a line listing of relevant information.
10. Formulate a hypothesis about a likely reservoir and mode of transmission.^a
11. Institute temporary control measures.
12. Perform a case-control study to develop epidemiologic evidence to support or refute the hypotheses.
13. Update control measures.
14. Document the reservoir and mode of transmission microbiologically. Confirm the relatedness of isolates using molecular genotyping techniques if necessary.^a
15. Document the efficacy of control measures.
16. Write a report and distribute it to appropriate individuals.
17. Change policies and procedures if necessary.

^aMolecular genotyping techniques may be employed early in the course of the investigation to evaluate the relatedness of pathogens associated with the cluster, reservoirs, and modes of transmission.

Policies and Procedures

Policies and procedures are necessary to optimize and standardize hospital routines and patient care practices. Certain generic policies and procedures apply to all departments, such as those for hand hygiene, isolation precautions, prevention of transmission of infectious diseases from and to visitors and health care workers, reprocessing of reusable patient care items, and disposal of medical waste. Other policies and procedures should be tailored to the potential infection risks relevant to specific departmental activities. Individual guidelines on various topics published by the CDC's HICPAC (<http://www.cdc.gov/hicpac/pubs.html>), a compendium of guidelines on the prevention of HCAs in acute care hospitals published by the Society for Healthcare Epidemiology of America (SHEA),^{100,199,209,366,426,468,618} and guidelines published by other professional societies serve as useful references for these efforts.

However, merely developing policies, procedures, and standardized practices is insufficient. Achievements in the prevention of HCAs primarily have resulted from reliably incorporating evidence-based practices into routine patient care. Effective leadership and application of principles and practices of implementation and improvement science are critical to the success of this effort.^{324,627,628}

Hand Hygiene

Proper hand hygiene, which includes handwashing using soap and water and hand antisepsis using a waterless, alcohol-based agent, reduces carriage of potential pathogens on the hands of health care workers.^{80,561} Hand hygiene is widely regarded as the quintessential infection prevention measure.

Indications and procedures for hand hygiene are reviewed in detail in the SHEA and HICPAC guidelines and a guidance document produced under the auspices of the World Health Organization (WHO).^{80,209,639} The WHO approach was developed as a user-centric model and has five moments for hand hygiene: before patient contact; before performing an aseptic task, after actual or potential contact with body fluids, after contact with the patient or his or her immediate surroundings, and after contact with the patient care environment outside the immediate

surroundings.⁶³⁹ The WHO has also provided a strategy for measurement of adherence with the five moments and behavior change strategies to improve adherence.^{638,768}

Handwashing with soap and water must be performed when hands are visibly soiled to remove organic material and associated microorganisms. When hands are not visibly soiled, hand antisepsis using an alcohol-based, waterless product is preferred because it reduces the number of pathogenic bacteria that transiently colonize the hands more effectively than handwashing.^{80,562} Hand hygiene is also necessary after removing gloves—an indication that many health care professionals fail to fully appreciate—because gloves can have macroscopic and microscopic holes that lead to hand contamination and because hands can be contaminated in the process of removing soiled gloves.³⁷¹

Individuals wearing artificial nails are more likely to harbor pathogenic gram-negative bacilli and yeast on their fingertips, and these organisms are less effectively cleared from artificial nails by use of an alcohol-based agent than from natural nails.^{297,480} Use of artificial nails or nail wraps was associated with carriage of *P. aeruginosa* on the hands of health care workers and infection among high-risk infants in a neonatal ICU.^{222,275} For these reasons, the HICPAC hand hygiene guideline recommends that health care workers not wear artificial fingernails or extenders when providing patient care and that natural nails should be kept less than 0.25 inches long.^{80,21}

Isolation Precautions

Proper use of isolation precautions is important for all health care facilities but especially critical in facilities caring for pediatric patients. Children hospitalized as the result of infections acquired in the community represent a substantial proportion of pediatric admissions, and transmission of these infections to other susceptible patients is a significant problem (see [Spread of Communicable Infections in Health Care Facilities](#)). Effective use of appropriate isolation precautions markedly reduces transmission of these agents.

HICPAC isolation guideline recommends the use of two tiers of precautions: standard precautions and transmission-based precautions.^{668,667}

Standard Precautions

Standard precautions synthesize the goals of protecting health care workers from bloodborne pathogens and protecting health care workers and patients from transmission of microorganisms from moist body substances.⁶⁶⁸ Standard precautions apply to any planned or potential contact with blood; all body fluids, secretions, and excretions except sweat, regardless of whether they contain visible blood; nonintact skin; mucous membranes; and supplies, equipment, or surfaces contaminated with these substances (see [Box 244.1](#)). Standard precautions should be used in the care of all patients at all times, regardless of their diagnosis or presumed infection status.⁶⁶⁸

Transmission-Based Precautions

Other precautions are needed to prevent transmission of contagious diseases (e.g., varicella, measles, tuberculosis, pertussis) and other epidemiologically important microorganisms (e.g., multidrug-resistant microorganisms, *C. difficile*) from infected or colonized patients. Transmission-based precautions are designed to provide the necessary measures in addition to those already specified by standard precautions to interrupt known modes of transmission of these microorganisms.⁶⁶⁸ The three types of transmission-based precautions are airborne, droplet, and contact precautions (see [Box 244.2](#)).

1. Airborne precautions are designed to prevent transmission of microorganisms spread by droplet nuclei (e.g., measles, varicella, tuberculosis), which can be carried on air currents over substantial distances.⁶⁶⁸ Special air handling and ventilation are required.⁶⁶⁸
2. Droplet precautions are designed to prevent transmission of microorganisms spread by large respiratory droplets that travel only short distances before settling.⁶⁶⁸ Special air handling and ventilation are not required.
3. Contact precautions are designed to prevent transmission of microorganisms spread by direct and indirect contact.⁶⁶⁸

Because some infections are spread by more than one mode of transmission, types of precautions may need to be combined (e.g.,

varicella requires airborne precautions and contact precautions). Patients infected or colonized with more than one microorganism also may require a combination of systems.

The HICPAC guideline lists clinical syndromes and conditions warranting empiric use of transmission-based precautions in addition to standard precautions to prevent transmission of epidemiologically important pathogens until infection with these microorganisms is excluded.⁶⁰⁹ To ensure that appropriate empiric precautions are implemented promptly, hospitals must have systems in place to evaluate patients for these infections as a part of their routine preadmission and admission care.

Visitors

Visitors with communicable diseases can inadvertently expose hospitalized patients and health care workers unless procedures to identify and exclude them are in place. Varicella, measles, and tuberculosis are the most problematic infections because they are spread by airborne transmission, enabling infected visitors to expose a large number of individuals in a short period. Visitors with pertussis, viral respiratory and gastrointestinal infections, parvovirus B19 infection, rubella, and mumps can pose a significant hazard to patients and health care workers with whom they have close contact.

Procedures to identify potentially infected visitors should include visiting children because they are the most likely people to be infected with these agents. Adult visitors and parents or guardians of visiting children should be asked a set of screening questions about fever, rash, respiratory and gastrointestinal symptoms, and recent exposure to other children with chickenpox, measles, or whooping cough. People without significant symptoms or exposures should be allowed to visit with no restrictions. Those who are otherwise well but have a recent history of a minor illness may be allowed to visit but potentially with restrictions, such as no visits by child visitors to the activity room and no sharing of food, drinks, or toys. People with fever, symptoms consistent with active respiratory or gastrointestinal infections, or rash consistent with a viral exanthem should not be allowed to visit. Individuals with significant exposures to chickenpox or measles who are susceptible to these infections and those with exposure to pertussis who may be in the incubation period of the disease should not be allowed to visit. This screening process should be repeated each day that the person visits the hospital. This procedure does not guarantee that people are not in the incubation phase of a contagious disease at the time of their visit (e.g., varicella) but can be useful in limiting exposures.

Many pediatric facilities implemented blanket restrictions on visitation by children during the influenza A H1N1 pandemic of 2009.⁶¹² Some facilities impose annual restrictions on visitation by young children during winter to prevent transmission of respiratory virus infections, but the nature, frequency and effect of these restriction policies have not been described.

SHEA published an expert guidance document providing recommendations for hand hygiene and use of barrier precautions by visitors.⁵⁰⁸ It recommends use of contact precautions by visitors to patients colonized or infected with extensively drug-resistant, gram-negative organisms and possibly by visitors of patients infected with enteric pathogens (e.g., *C. difficile*, norovirus). Use of contact precautions is not recommended for visitors to patients with MRSA or VRE. The guideline acknowledges that requirements for the use of barriers should be balanced by the potential negative psychosocial impact on children and interference with bonding, breastfeeding, and delivery of family-centered care and by practical concerns regarding enforcement.

Occupational Health

Health care workers require protection from the significant infectious risks inherent in patient care, and patients and other health care workers need to be protected from exposure to health care workers with communicable diseases. Integrating management and prevention strategies to accomplish these two goals requires close collaboration between hospital infection prevention and control programs and employee health departments. A HICPAC guideline for infection control in health care workers contains comprehensive recommendations

for evaluation of illnesses, postexposure evaluation and management, and prevention of occupationally acquired infections in health care workers.⁷⁰

Evaluation of Ill Health Care Workers

Hospital staff and volunteers with symptoms such as persistent fever, conjunctivitis, skin lesions or rashes, diarrhea, and persistent cough should be evaluated for a communicable disease. Possible cases of varicella, herpes zoster on an exposed area of the body, herpetic whitlow, adenoviral conjunctivitis, measles, mumps, rubella, pertussis, staphylococcal skin infection, enteric infection in a food service worker, and active pulmonary tuberculosis should be investigated promptly and confirmed with laboratory tests if necessary.

Many health care workers choose to have these problems evaluated by their primary care providers. However, employee health departments have an interest in completing or collaborating in these assessments, especially if there is a question about whether the condition was acquired in the workplace, requires a furlough from work, or might have exposed patients or other health care workers.

Postexposure Evaluation and Management of Health Care Workers

A structured approach to the assessment and management of exposures of health care workers to patients with infectious diseases is critical for promptly providing postexposure prophylaxis, if indicated, and to allay anxiety while avoiding unnecessary interventions and loss of workdays. The first step is to develop criteria for assessing the nature of the exposure because many reported encounters do not pose a significant risk of infection. Some exposures (e.g., varicella, hepatitis B) may require an assessment of the susceptibility of the health care worker to infection, and procedures should describe the indications for laboratory tests and the interpretation of results.

Postexposure prophylaxis regimens for various exposures are discussed in a HICPAC guideline,⁷⁰ and those for bloodborne infections are available in various other guidelines⁶⁴³ (<https://stacks.cdc.gov/view/cdc/20711>). Additional information for postexposure prophylaxis can be obtained by searching the Centers for Disease Control and Prevention website (<http://www.cdc.gov>). Counseling regarding the risks and consequences of the exposure is an important component of this service.

Prevention of Occupationally Acquired Infections by Health Care Workers

Because vaccination against infectious diseases is a highly cost-effective prevention strategy, hospitals should offer vaccinations free of charge. Vaccination against measles (or demonstration of immunity) has been regarded as a quality of care indicator for occupational health programs since 1994.³⁷⁶ In 2013, the CMS required acute care hospitals in the United States to report influenza vaccination of health care workers as part of the Hospital Inpatient Quality Reporting Program.

Yearly influenza vaccination of health care workers is recommended by the Advisory Committee on Immunization Practices.¹¹⁶ Although vaccination rates of health care workers have improved substantially, they remain suboptimal.⁴²¹ Interventions to improve vaccination rates are provision of vaccine free of charge, enhanced access to vaccination, reminders or incentives, active management of the vaccination program requiring active declination, and mandatory immunization policies. Mandatory immunization policies are most effective^{421,563}; however, despite endorsement by the American Academy of Pediatrics,¹⁸⁵ the Pediatric Infectious Diseases Society (PIDS), SHEA, and the Infectious Diseases Society of America (IDSA) (http://www.idsociety.org/uploadedFiles/IDSA_Policy_and_Advocacy/Current_Topics_and_Issues/Immunizations_and_Vaccines/Health_Care_Worker_Immunization/Statements/IDSA_SHEA_PIDS%20Policy%20on%20Mandatory%20Immunization%20of%20HCP.pdf), mandatory vaccination has not been adopted universally.

Given the significant occupational risk for hepatitis B infection in hospitals, hepatitis B vaccination should be offered routinely to health care workers.⁶⁴³ The OSHA bloodborne pathogens standard requires hospitals to offer free hepatitis B vaccination, and workers who do not wish to be vaccinated must sign a specific informed refusal. Other vaccines, such as the varicella vaccine and acellular pertussis vaccine,

can help to eliminate or at least drastically reduce occupational acquisition of these diseases.

In addition to hepatitis B vaccination, the OSHA bloodborne pathogens standard mandates other prevention measures, including the development of an exposure control plan that identifies employees with occupational risk for exposure to bloodborne pathogens; annual training for these individuals regarding the risk for bloodborne infection and prevention measures; provision of personal protective clothing and equipment; work practice controls, including equipment and procedures for the safe handling and disposal of needles and sharp instruments; and procedures for identification, transportation, storage, and disposal of contaminated items and waste.⁵³⁰

In 2005, The CDC published detailed guidelines to prevent and control transmission of *M. tuberculosis* to health care workers.³³⁹

Reprocessing of Reusable Patient Care Items

Many HCAI outbreaks have been related to use of contaminated equipment. Consequently, hospital infection prevention and control programs must work closely with all hospital departments reprocessing reusable patient care items to ensure proper selection, implementation, and quality monitoring of reprocessing methods.⁶¹⁴

Education and Training of Health Care Workers

Providing education and training in general principles and specific aspects of hospital infection prevention and control is one of the primary responsibilities of program staff. Staff members should be familiar with principles of adult learning, assessing the educational needs of the audience, defining learning objectives, determining optimal instructional formats, using effective teaching and communication skills, and weighing the merits of various educational tools.

Product Evaluation

Many new medical products are introduced to the health care market every year. Although some products have the potential to reduce infectious risks, data to substantiate the safety and efficacy claims of manufacturers often are limited. Many devices marketed to hospitals caring for children have never been tested in children. Because these products often are substantially more expensive than existing products, there must be a compelling rationale for their use. Infection prevention and control staff members can provide valuable assistance to hospital committees in assessing the potential benefits of new products and, when appropriate, can design and conduct appropriate product evaluations trials.

ANTIMICROBIAL STEWARDSHIP PROGRAMS IN HEALTH CARE FACILITIES

The rapid emergence of pathogens resistant to multiple antimicrobial agents (e.g., VRE, ESBL- and carbapenemase-producing gram-negative bacteria) and the widespread dissemination of these resistant microorganisms constitute an unprecedented worldwide crisis⁷⁵ (see <http://www.cdc.gov/drugresistance/threat-report-2013/> and <http://www.who.int/antimicrobial-resistance/events/UNGA-meeting-amr-sept2016/en/>). The mechanisms involved in the emergence and spread of antimicrobial resistance are complex but are no doubt facilitated by intense selective pressure caused by overuse and misuse in hospitals of antimicrobial agents, particularly newer, broad-spectrum agents.

Studies demonstrate that most hospitalized children, particularly in settings such as ICUs and transplantation units, receive empiric, targeted, or prophylactic treatment with antimicrobial agents.^{39,255,345} Hospitals that used higher volumes of antimicrobial agents are also more likely to use broad-spectrum agents.²⁵⁵ Inappropriate use of antimicrobial agents is common,^{416,553} although the definition of the term *appropriateness* is not standardized and is subject to interpretation.^{180,606}

In 2007, IDSA and SHEA published a guideline for institutional antimicrobial stewardship programs (ASPs).¹⁷⁴ In 2012, the IDSA, SHEA, and PIDS published a policy statement on antimicrobial stewardship.⁶⁸⁶ Children's hospitals responded by developing ASPs.⁵¹⁸ A 2014 NHSN survey of acute care hospitals in the United States reported that 50% of the 76 responding children's hospitals had an ASP that contained

BOX 244.4 Centers for Disease Control and Prevention Core Elements of Hospital Antibiotic Stewardship Programs^a

1. Leadership commitment: Dedicate necessary human, financial, and information technology resources.
2. Accountability: Appoint a physician leader responsible for program outcomes.
3. Drug expertise: Appoint a pharmacist leader responsible for working to improve antibiotic use.
4. Action: Implement recommended actions.
5. Tracking: Monitor antibiotic prescribing and resistance patterns.
6. Reporting: Report information on antibiotic use and resistance regularly to doctors, nurses, and relevant staff.
7. Education: Educate clinicians about resistance and optimal prescribing.

^aDescribed in more detail at <http://www.cdc.gov/getsmart/healthcare/implementation/core-elements.html>.

Modified from Pollack LA, Srinivasan A. Core elements of hospital antibiotic stewardship programs from the Centers for Disease Control and Prevention. *Clin Infect Dis*. 2014;59(suppl 3):S97–S100.

all seven of the CDC's Core Elements of Hospital Antibiotic Stewardship Programs.⁵⁶⁷ A comparative analysis of children's hospitals with or without a formal ASP demonstrated lower use of all antimicrobial agents in hospitals that had a formal ASP.³⁰¹

The Core Elements of Hospital Antibiotic Stewardship Programs⁵⁶⁸ are summarized in Box 244.4 and described in more detail on the CDC website (<http://www.cdc.gov/getsmart/healthcare/implementation/core-elements.html>). The CDC has collaborated with the National Quality Forum to develop a playbook for ASPs based on these core elements (http://www.qualityforum.org/Publications/2016/05/Antibiotic_Stewardship_Playbook.aspx). All acute care hospitals receiving reimbursement by CMS and accreditation by The Joint Commission are required to have an ASP based on these core elements.

In 2016, SHEA and IDSA published comprehensive evidence-based guidelines for implementation and measurement of antibiotic stewardship interventions for inpatient populations. The guideline provides detailed recommendations that expand particularly on strategies and interventions that address the Action component of the CDC's Core Elements. Augmenting this guidance is a growing literature on addressing antimicrobial stewardship for hospitalized children, including patient populations, conditions, and antimicrobials that represent appropriate targets and effective interventions to improve antimicrobial use for these targets.^{254,262,301,378,606,605,681}

Active Immunizing Agents

Penelope H. Dennehy • Ian C. Michelow • Michael P. Koster •
Michael A. Smit • Jerome Larkin

Prevention of infectious diseases in children by immunization is one of the outstanding accomplishments of medical science. Children enjoy better health today because of effective immunization programs, which in many countries have markedly diminished the morbidity and mortality of previously common contagious diseases. The striking decline in the United States in vaccine-preventable childhood diseases is demonstrated in Table 245.1.⁴ Immunization programs have led to the global eradication of smallpox, elimination of measles and poliomyelitis in some regions of the world, and substantial reductions in the morbidity and mortality attributed to diphtheria, tetanus, and pertussis. The World Health Organization (WHO) estimates that 2 to 3 million child deaths are prevented by vaccinations annually (<http://www.who.int/mediacentre/factsheets/fs378/en/>).

To achieve this progress in child health, scientific technology and medical practice have combined efforts to (1) understand the biology of causal infectious agents, (2) purify these agents and some of their components, (3) develop and test safe and effective vaccines, (4) manufacture and administer the vaccines to appropriate segments of the population, (5) develop appropriate indications and implement schedules for immunizations, and (6) identify necessary contraindications.

Infectious diseases can be prevented through immunization by stimulating an active immunologic defense (e.g., from humoral antibody) through the administration of antigens, usually before natural exposure to an infectious agent (i.e., active immunization) or by temporarily supplying preformed human or animal antibody to persons before or soon after exposure to certain infectious agents (i.e., passive immunization). Active immunizations, including the currently available vaccines, are discussed in this chapter. The composition of major vaccines and their routes of administration are listed in Table 245.2.

ACTIVE IMMUNOPROPHYLAXIS: CONSIDERATIONS AND RECOMMENDATIONS

Vaccines

An ideal immunizing agent should include several characteristics. The agent should be easy to produce in well-standardized preparations that

are readily quantifiable and stable in immunobiologic potency. It should be easy to administer and not produce disease in the recipient or susceptible contacts. It should induce long-lasting (ideally permanent) immunity that is measurable by available and inexpensive techniques. It should be free of contaminating and potentially toxic substances, and adverse reactions should be minimal and have minor consequences. All of these objectives rarely, if ever, are met with the currently available vaccines because they are neither completely safe nor completely effective. Partial immunity or undesirable side effects or reactions, or both, including rare severe reactions, can occur. Nonetheless, vaccines in current use are highly effective and very safe.

All active immunizing agents (i.e., vaccines) contain one or more antigens that stimulate a protective immunologic response. Some are live attenuated viruses or bacteria; other vaccines consist of killed microorganisms or contain inactivated components such as exotoxins (i.e., toxoids). In some vaccines, the antigen is a highly defined, single constituent, such as *Haemophilus influenzae* type b (Hib) polysaccharide, whereas in others, the antigen component is less well defined, such as live viruses or whole-cell pertussis vaccines composed of killed *Bordetella pertussis* organisms.

Immunizing agents are administered in suspending fluids such as sterile water, saline solution, or complex tissue culture fluid that can contain proteins or other constituents from the medium from which the vaccine was produced (e.g., serum proteins, egg antigens, other tissue culture–derived antigens). Certain preservatives, stabilizers, or antibiotics are added to some vaccines, and in some cases, the additives can result in hypersensitivity reactions. To enhance immunogenicity, particularly for vaccines containing inactivated microorganisms or their extracted components, adjuvants such as aluminum compounds are added.

Immunization Schedules

The vaccinee's age and timing of immunization are critical for the success of vaccination. The vaccine schedule is based on many factors, including the epidemiology of naturally occurring disease, age-specific risk of complications caused by the natural disease, anticipated immunologic

TABLE 245.1 Reduction in Morbidity of Some Vaccine-Preventable Diseases in the United States

Disease	Maximum No. of Cases (y)	Cases in 2015	% Decrease
Diphtheria	206,939 (1921)	0	100
Pertussis	265,269 (1934)	20,762	92
Tetanus	1314 (1922–1926)	29	98
Poliomyelitis, paralytic	21,269 (1952)	0	100
Measles	894,134 (1941)	188	>99
Mumps	152,209 (1968)	1329	>99
Rubella	57,686 (1969)	5	>99
Congenital rubella syndrome	20,000 (1964–1965)	1	>99
<i>Haemophilus influenzae</i> type b	20,000 (before 1987)	29	>99
Invasive pneumococcal disease (>5 y)	15,933 (2000)	1177	93
Hepatitis B	21,102 (1990)	3370	84
Varicella	158,364 (1992)	9789	94

Meningococcal conjugate (MCV4)	Bacterial polysaccharide-protein conjugate	IM
Meningococcal serogroup B (MenB)	Bacterial lipoprotein	IM
MMR	Live attenuated viruses	SC
MMRV	Live attenuated viruses	SC
Pneumococcal polysaccharide (PPSV23)	Bacterial polysaccharide	IM or SC
Pneumococcal conjugate (PCV13)	Bacterial polysaccharide-protein conjugate	IM
Poliovirus (IPV)	Inactivated viruses	IM or SC
Rabies	Inactivated virus	IM
Rotavirus (RV1 and RV5)	Live attenuated viruses	oral
Tdap	Toxoids and inactivated bacterial components	IM
Tetanus	Toxoid	IM
Typhoid	Bacterial capsular polysaccharide	IM
Typhoid	Live attenuated bacteria	Oral
Varicella	Live attenuated virus	SC
Yellow fever	Live attenuated virus	SC

^aOnly major childhood vaccines and selected others are included.

BCG, Bacille Calmette-Guérin (tuberculosis); DT, diphtheria-tetanus toxoids (for children <7 y); DTaP, diphtheria-tetanus toxoids–acellular pertussis vaccine (for children <7 y); Hib, *Haemophilus influenzae* type b conjugate vaccine; ID, intradermal; IM, intramuscular; IPV, inactivated poliovirus vaccine; MMR, live measles-mumps-rubella viruses vaccine; MMRV, live measles-mumps-rubella-varicella viruses vaccine; SC, subcutaneous; Td, tetanus-diphtheria toxoid (for children ≥7 y and adults); Tdap, diphtheria–reduced tetanus toxoids–acellular pertussis vaccine (for children ≥10 y and adults).

response of the host to the antigens, duration of immunity that can be induced, and recommended ages for routine health care visits. Vaccines are recommended at the youngest age at which significant risk for the natural disease and its complications exist and at which a protective immunologic response to the vaccine can occur.

An example is measles vaccine, which in the United States is recommended routinely at 12 to 15 months of age because in the first year of life many children have residual, transplacentally acquired maternal measles serum antibody that interferes with the antibody response. However, during measles outbreaks or for travel of infants to measles-endemic areas, measles vaccination is recommended for infants as young as 6 months because the risk of complications with measles is high among children younger than 1 year.^{38,471} These infants should be vaccinated again at 12 to 15 months of age. Similarly, in countries where measles causes significant morbidity and mortality for infants younger than 9 months, the Global Advisory Group of the WHO's Expanded Programme on Immunization (EPI) has recommended giving measles vaccine to infants as young as 6 months of age.⁶⁹⁷

The recommended doses of vaccine are determined by the number necessary to achieve a uniform and predictable immunologic response and to sustain protection. Some immunizing agents require the administration of more than one dose for development of an adequate antibody response and require a booster dose to maintain protection. Examples are pertussis, diphtheria, and tetanus vaccines. Intervals between doses are based on the kinetics of primary and secondary antibody responses.

Route of Administration

An example of the effect of the route of administration on immunologic response is provided by poliomyelitis vaccines. Inactivated poliovirus vaccines given intramuscularly induce systemic immunity through serum antibody production, but they do not consistently evoke local secretory immunoglobulin A (IgA) antibodies in the intestinal tract and thereby effectively prevent subsequent transmission of wild-type virus. Because live attenuated oral polio vaccine (OPV) induces optimal intestinal and systemic antibody, it was the preferred vaccine for routine immunization of children in the United States against poliomyelitis for 3 decades and remains the recommended vaccine by the WHO for global eradication.⁷⁰¹ Vaccines containing adjuvants must be injected deep into the muscle mass because if they are administered subcutaneously or intradermally, they can cause local irritation, inflammation, granuloma formation, or necrosis.^{29,408}

Injectable vaccines should be administered in areas unlikely to cause local neural, vascular, or tissue injury (Table 245.3).^{29,408} Although the upper, outer quadrant of the buttocks has been used as a frequent site of immunization, this area ordinarily should not be used because the gluteal region consists mostly of fat in young children and because of potential injury to the sciatic nerve. Ideally, intramuscular injections should be given in the anterolateral aspect of the upper part of the thigh or the deltoid muscle of the upper part of the arm. The anterolateral aspect of the thigh is preferred for infants because of its muscle mass relative to other sites. For older children, the deltoid muscle usually is sufficiently large for intramuscular injection. The incidence of significant pain in 18-month-old children injected intramuscularly in the thigh is greater than that after deltoid injections and can result in transient limping.³⁶³ The deltoid is the preferred site for intramuscular administration of vaccines in children 18 months of age or older, although some physicians prefer the anterolateral aspect of the thigh for toddlers.^{29,408}

Subcutaneous inoculations usually should be given in the thigh of infants and the deltoid area of older children. Intradermal vaccines should be administered on the volar aspect of the forearm.

Recommended routes for administration of vaccines are provided in their package inserts and are summarized in recommendations for immunizations by the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP)²⁹ and the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC).⁴⁰⁸

Vaccine Dose

The recommended dose of each immunizing agent is derived from theoretical considerations and vaccine trials. Because inactivated

TABLE 245.3 Site and Needle Length by Age for Intramuscular Immunization

Age Group	Needle Length, inches (mm)	Suggested Injection Site
Neonate (preterm and term) and infants age <1 mo	$\frac{5}{8}$ (16)	Anterolateral thigh muscle
Term infant, age 1–12 mo	1 (25)	Anterolateral thigh muscle
Toddlers and children	$\frac{5}{8}$ – 1 (16–25)	Deltoid muscle of the arm
	1 – 1 $\frac{1}{4}$ (25–32)	Anterolateral thigh muscle
Adolescents and young adults		
Female and male, <60 kg	1 (25)	Deltoid muscle of the arm
Female, 60–70 kg	1 (25)	Deltoid muscle of the arm
Female, 70–90 kg	1 (25) – 1 $\frac{1}{2}$ (38)	Deltoid muscle of the arm
Female, >90 kg	1 $\frac{1}{2}$ (38)	Deltoid muscle of the arm
Male, 70–118 kg	1 (25) – 1 $\frac{1}{2}$ (38)	Deltoid muscle of the arm
Male, >118 kg	1 $\frac{1}{2}$ (38)	Deltoid muscle of the arm

Modified from American Academy of Pediatrics. Active immunization. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:1–56.

immunizing agents cannot replicate in the host, these vaccines must contain an adequate antigenic mass to stimulate the desired immunologic response. Long-lasting immunity with these vaccines requires repeated doses. Exceeding the recommended dose can be hazardous because of excessive local or systemic concentrations of immunizing agents, whereas administration of doses smaller than those recommended may result in inadequate response and protection.^{29,408}

Lapsed Immunizations

Intervals between multiple doses of an antigen longer than those recommended do not affect the antibody responses achieved, provided the immunization series is completed. Restarting the series after interruption of the vaccine schedule or giving additional doses is not necessary.

Simultaneous Administration of Multiple Vaccines

Because most vaccines can be given simultaneously without impairing effectiveness or safety, multiple vaccines are given to children concurrently.³⁹² Simultaneous administration of vaccines is particularly important for inadequately immunized children whose return for further immunization is doubtful or for patients with imminent travel plans.

An inactivated vaccine and a live virus vaccine can be administered simultaneously at different sites without interference with the immune response. Exceptions are yellow fever and cholera vaccines because antibody responses are diminished if they are administered simultaneously. If possible, administration of these vaccines should be separated by at least an interval of 3 weeks.⁴⁰⁸ In the case of live virus vaccines, the immune response to one live virus vaccine can be impaired if it is given within 4 weeks of another.⁴⁰⁸ Parenteral live virus vaccines not administered on the same day should be given at least 4 weeks apart. This consideration is the basis of the recommended minimal interval of 1 month (i.e., 4 weeks) between doses of measles vaccine, such as for a previously unimmunized person who is entering college. Guidelines for spacing live and killed antigen vaccines are given in Table 245.4.

TABLE 245.4 Guidelines for Spacing the Administration of Live and Inactivated Antigens

Antigen Combination	Recommended Minimum Interval Between Doses
Two or more inactivated ^a	None; can be administered simultaneously or at any interval between doses
Inactivated plus live	None, can be administered simultaneously or at any interval between doses
Two or more live injectible ^b	28-day minimum interval, if not administered simultaneously

^aIn people with functional or anatomic asplenia, quadrivalent meningococcal conjugate vaccine (MCV4-D; Menactra) should not be given until at least 4 weeks after all doses of 13-valent pneumococcal conjugate vaccine (PCV13) have been administered because of interference with the immune response to the PCV13 series because both vaccines are conjugated to diphtheria toxin carrier protein. PCV13 and 23-valent pneumococcal polysaccharide vaccine (PPSV23) should not be administered simultaneously and should be spaced at least 8 weeks apart; when both vaccines are indicated, PCV13 should be administered first, if possible.

^bAn exception is made for some live oral vaccines (e.g., Ty21a typhoid vaccine, oral poliovirus vaccine, oral rotavirus vaccine) that can be administered simultaneously or at any interval before or after inactivated or live parenteral vaccines.

Modified from American Academy of Pediatrics. Active immunization. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:1–56.

Record Keeping, Patient Information, Informed Consent, and Reporting

Accurate record keeping by physicians is required, and parents (or patients) should keep up-to-date immunization records for their children. The 1986 National Childhood Vaccine Injury Act (NCVIA) requires that for routinely recommended childhood vaccines, health care providers record in the child's permanent medical record the date of administration of the vaccine, manufacturer, lot number, and name of the health care provider administering the vaccines.²⁹

All children and their parents or caregivers should be informed about the benefits and risks of the vaccines to be administered. For vaccines currently specified in the NCVIA, Vaccine Information Statements (VISs) have been prepared by the CDC and must be used by vaccine administrators.

Informed consent should be obtained before the administration of vaccines. Some physicians and other health care providers may choose to obtain the parent's signature, but current law does not require written consent. An appropriate alternative to written consent is to note in the patient's record that the VISs have been provided and discussed with the parent, patient, or legal guardian.²⁹

To increase knowledge about adverse reactions, all temporally associated events severe enough to require the patient to seek medical attention should be reported to the Vaccine Adverse Events Reporting System (VAERS); VAERS forms can be obtained by calling 800-822-7967 or by accessing the website (<http://vaers.hhs.gov>). Health care providers who administer vaccines are required in the United States to report to the VAERS specific adverse events in recipients of the vaccines covered by the NCVIA (Health Resources and Services Administration: <http://www.hrsa.gov/vaccinecompensation/vaccinetable.html>). This system for reporting adverse events associated with vaccination was established by the US Department of Health and Human Services to foster recognition of vaccine-related reactions and further study to establish possible causation.

Decreased occurrence of vaccine-preventable infectious diseases has resulted in a greater number of adverse events temporally related to immunization than cases of disease. Although in some cases, such as vaccine-associated paralytic poliomyelitis, vaccine has been established as the cause, in other circumstances, such as brain damage alleged to be attributed to whole-cell pertussis vaccine, causation by vaccine has not been proved.¹⁴

Increased public visibility of vaccine reactions contributed to a marked increase in vaccine litigation in the 1980s as compensation was

sought through the judicial system by those alleged to have suffered serious vaccine-related sequelae. A marked increase in manufacturers' actual and anticipated liability costs and subsequent escalating increases in the price of vaccines occurred concomitantly. These and other developments, such as threats to the vaccine supply, concerns by parents about vaccine safety, and recognition of the benefits derived from improved coordination and planning of vaccine programs, led to passage of the 1986 NCVIA and the National Vaccine Injury Compensation Program (<https://www.hrsa.gov/vaccinecompensation/index.html>), a no-fault system to compensate victims of certain presumed vaccine-related events.

The Department of Health and Human Services administers the compensation program. Decisions on compensation are made by the US Court of Federal Claims and are based on the Vaccine Injury Table, which was revised since passage of the original legislation in response to new findings and analysis by several Institute of Medicine (IOM) committees. Compensation for injuries occurring after the program's effective date of October 1, 1988, is provided by excise taxes on each vaccine. The program has been successful in reducing vaccine-related litigation, stabilizing vaccine prices, and creating a favorable environment for the introduction of new vaccines.²⁶²

Vaccine Recommendations and Schedules

In developing recommendations for immunization, many factors are considered, including the vaccine's characteristics, scientific knowledge about the principles of immunization, assessment of the benefits of the vaccine, the risk of the disease and its complications, vaccine costs, and risk of adverse reactions. Changes in relative benefits and risks necessitate continued review of recommendations.

In the United States, recommendations for immunization of infants and children are made by the ACIP of the CDC and the AAP's Committee on Infectious Diseases. These committees work closely together, and in most circumstances, their recommendations are similar. The two committees and the American Academy of Family Practice (AAFP) issue a single vaccine schedule each year. The 2016 schedule for routine administration of childhood vaccines is given in [Fig. 245.1](#) and [Table 245.5](#).

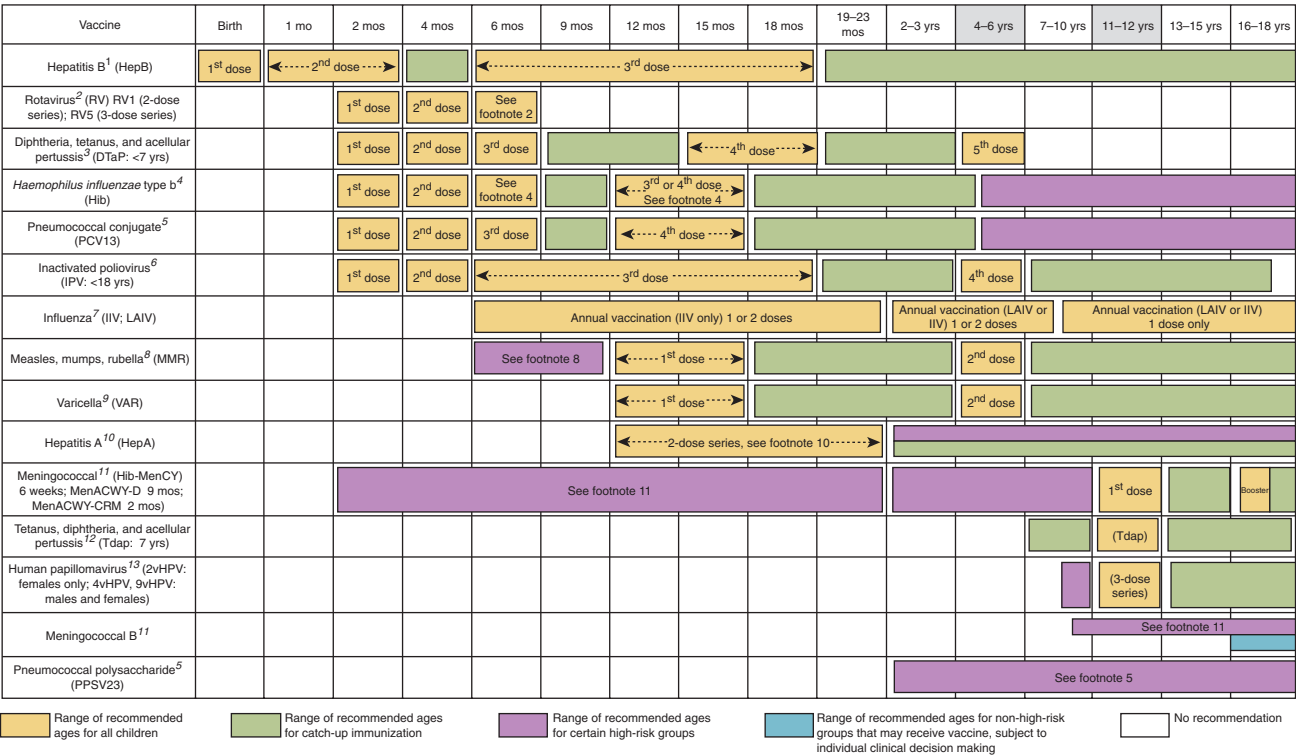

A major change in 1996 was the establishment of a routine preadolescent immunization visit at 11 to 12 years of age.¹²⁵ The dose of adult tetanus-diphtheria–acellular pertussis (Tdap) vaccine should be given at that time, as should a dose of the meningococcal conjugate vaccine and the first dose of human papillomavirus (HPV) vaccine. At this preadolescent visit, children not previously vaccinated with hepatitis B, varicella, or the second dose of measles-containing vaccine (or any combination of these vaccines) should be given the necessary immunizations and scheduled for future visits to receive any vaccines not administered during this visit.

Other countries have similar national mechanisms for formulating immunization schedules and recommendations that are based on the local epidemiology of diseases and available vaccines. In low-resource countries, practices are guided by the WHO's EPI. Current recommendations are listed at the website (http://www.who.int/immunization/policy/Immunization_routine_table2.pdf?ua=1).

As new vaccines and scientific knowledge become available, vaccine recommendations and schedules are modified and changed. Examples of changes in the past 2 decades include the use of pneumococcal conjugate vaccine beginning at 2 months of age, universal toddler hepatitis A immunization, and recommendations for administration of a second dose of varicella vaccine, and the introduction of acellular pertussis vaccines for adolescents and adults.

Implementation of Vaccine Programs

In addition to the availability of safe and effective vaccines and appropriate schedules for their use, effective means of implementation and delivery are necessary for the success of vaccine programs. In the United States, high rates of immunization among school-aged children have been achieved, in part because of public health programs for vaccine administration, government support for vaccine purchase, and state laws requiring immunization for school entry. In contrast to rates of approximately 95% or higher among school-aged children, immunization

This schedule includes recommendations in effect as of January 1, 2016. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant advisory committee on immunization practices (ACIP) statement for detailed recommendations, available online at <http://www.cdc.gov/vaccines/hcp/acip-recs/index.html>. Clinically significant adverse events that follow vaccination should be reported to the vaccine adverse event reporting system (VAERS) online (<http://www.vaers.hhs.gov>) or by telephone (800-822-7967). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (<http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm>) or by telephone (800-CDC-INFO [800-232-4636]).

This schedule is approved by the advisory committee on immunization practices (<http://www.cdc.gov/vaccines/acip/>), the American academy of pediatrics (<http://www.aap.org>), the American academy of family physicians (<http://www.aafp.org>), and the American college of obstetricians and gynecologists (<http://www.acog.org>).

NOTE: The above recommendations must be read along with the footnotes of this schedule.

FIG. 245.1 Recommended immunization schedule for people from birth to 18 years of age in the United States in 2016. An expanded version of the table and its 13 footnotes can be found at <https://www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html>. (From Centers for Disease Control and Prevention. Immunization schedules. <http://www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html>.)

rates for infants and young children in the 1980s were significantly lower.⁷¹³ In a survey of 21 primarily urban areas throughout the United States, 11% to 58% (median, 44%) of children who entered school in 1991 and 1992 were fully vaccinated by their second birthday. Failure to immunize young children was a major factor in the outbreaks of measles in major urban areas in the United States in 1989 through 1991.⁶³⁴

The measles epidemic and the recognition of low immunization rates prompted a national campaign to achieve the US Public Health Service's goal of a 90% vaccine coverage rate for children by the time they were 2 years of age. Initiatives have included improved access to vaccines, education of health care providers in the community, and the development of standards for pediatric immunization practice.⁴⁹⁸ The standards have been endorsed by the AAP, AAFP, and other major professional organizations and serve as guidelines to be followed for improving the delivery of vaccines. They include evaluation of the patient's immunization status at all medical visits, use of valid contraindications, simultaneous administration of all indicated vaccines, and routine audits of the immunization status of patients by providers. These and other initiatives resulted in increasing immunization rates among young children.

According to the National Immunization Survey, coverage rates for children 19 to 35 months of age in 2015 were 72.2% for completion of the combined vaccine series, which includes four or more doses of diphtheria, tetanus toxoids, and acellular pertussis vaccine (DTaP); three or more doses of poliovirus vaccine; one or more doses of measles-containing vaccine; full series of Hib vaccine (i.e., three or four doses, depending on product type); three or more doses of hepatitis B vaccine (HepB); one or more doses of varicella vaccine; and four or more doses

of pneumococcal conjugate vaccine (PCV).³⁴⁴ Vaccination coverage rates in the United States for preschool-aged children consistently have been greater than 70% since 2013.

Vaccine Contraindications, Precautions, and Use in Special Circumstances

Recommendations for the use of specific vaccines include contraindications and use in special circumstances, such as immunocompromised patients (from underlying disease or therapy such as high-dose corticosteroids) and pregnancy.^{29,408} Established, generic contraindications are moderate or severe illness, a previous anaphylactic reaction to the specific vaccine, and a severe hypersensitivity reaction (e.g., anaphylaxis) to a vaccine constituent.

The decision to defer immunization in a febrile child should be based on the physician's assessment of the severity of the illness rather than the degree of fever. Children with minor illness and low-grade fever usually should be vaccinated, especially if a child is unlikely to return promptly for the deferred immunization.

Administration of live virus vaccines such as varicella and measles-mumps-rubella (MMR) vaccines usually is contraindicated in patients with altered immunity. However, the morbidity and mortality rates of measles and the lack of complications from vaccination of children infected with human immunodeficiency virus (HIV) prompted recommendations that these children, unless significantly immunocompromised, receive the MMR vaccine.^{17,126,471}

Because of a theoretical risk to the developing fetus, administration of live virus vaccines in most cases is not recommended for pregnant women.^{36,408} However, inadvertent administration of vaccine is not necessarily a reason for termination of the pregnancy, and some live

TABLE 245.5 Catch-Up Immunization Schedule for People Age 4 Months Through 18 Years Who Start Late or Are >1 Month Behind—United States, 2017^a

Vaccine	Minimum Age for Dose 1	MINIMUM INTERVAL BETWEEN DOSES			
		Dose 1 to 2	Dose 2 to 3	Dose 3 to 4	Dose 4 to 5
Children 4 Months–6 Years of Age					
Hepatitis B ¹	Birth	4 wk	8 wk <i>and</i> at least 16 wk after first dose Minimum age for the final dose is 24 wk	—	—

From Centers for Disease Control and Prevention. Immunization schedules. <http://www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html>.

virus vaccines, such as those for yellow fever and poliomyelitis, can be given safely to pregnant women. Inactivated bacterial and viral vaccines such as tetanus toxoids, hepatitis B, and influenza vaccine, which are composed of antigenic components or killed organisms, can and should be given during pregnancy if indicated.

In some recipients, vaccines can cause severe reactions, which may be a contraindication or precaution to subsequent administration of the specific vaccine. An example is a child in whom a fever of 40.5°C (105°F) or higher develops after receiving DTaP vaccine and for whom administration of further doses of pertussis-containing vaccine is not indicated in most cases. This recommendation is based on the unproven but reasonable presumption that children who experience adverse reactions after receiving pertussis immunization are at risk for similar reactions of equal or greater magnitude on subsequent immunization.¹⁸⁸

Anaphylactic reactions caused by allergenic components of a vaccine (e.g., gelatin or egg protein in vaccine prepared in embryonated chicken eggs) have occurred rarely. Vaccines posing a potential risk for egg-sensitive people include those against measles, mumps, inactivated influenza, and yellow fever. Before administering vaccines to people with possible hypersensitivity to vaccine constituents, physicians should review current recommendations for these vaccines. In other circumstances, specific immunizations may be contraindicated because of previous reactions and the child's medical history, such as with DTaP (e.g., evolving neurologic disorders) and MMR (e.g., immune thrombocytopenia associated temporally with vaccination).⁴⁰⁸

Misconceptions

Appropriate and safe use of vaccines requires knowledge of the patient's relevant medical history, adverse reactions associated with previous receipt of vaccines, and specific indications and contraindications. Without this information, vaccines may be administered inadvertently or not given in circumstances in which immunization is indicated, thereby resulting in missed opportunities for receiving the recommended immunization and susceptibility of the child to a preventable disease. Examples of common misconceptions concerning contraindication to vaccines are given in Box 245.1.

International Travel

Foreign travel often is an indication for giving vaccines not routinely administered to children. The risk of exposure to certain vaccine-preventable diseases may be greater than in the United States, and travelers may be exposed to infections that are uncommon or do not occur in the United States. Examples include vaccines against hepatitis A, typhoid fever, yellow fever, and Japanese encephalitis (JE) (Table 245.6), depending on the location and circumstances of the person's visit. Some countries may require yellow fever vaccination for entry. The second dose of measles vaccine should be given to children and adolescents who have received only one dose (provided 4 weeks or more have elapsed since administration of the first dose), irrespective of age because the risk of exposure to measles cases may be substantial in some foreign countries. Children and adolescents should have received all vaccines routinely recommended for their age.

Information on vaccine requirements for international travel is provided in a semiannually revised publication by the CDC, *Health Information for International Travel*⁶⁷⁸ (<https://wwwnc.cdc.gov/travel/page/yellowbook-home>). Information also is available from the CDC International Travelers Hotline (800-232-4636) or the CDC Traveler's Health website (<http://wwwnc.cdc.gov/travel/>).

Vaccine Safety

Immunizations are among the most cost-effective and widely used public health interventions. Public health recommendations for vaccine programs and practices represent a dynamic balancing of risks and benefits. Vaccine safety or risk monitoring is necessary to weigh these factors accurately and adjust vaccination policies accordingly.

No vaccine is perfectly safe or effective. As the incidence of vaccine-preventable diseases is reduced, public concern refocuses from the risk of contracting disease to the health risks associated with vaccines. A higher standard of safety typically is expected for vaccines compared

BOX 245.1 Misconceptions About Vaccine Contraindications

- Mild acute illness with low-grade fever or mild diarrheal illness in an otherwise well child.
- Current antimicrobial therapy or the convalescent phase of illness.
- Reaction to previous vaccine dose that involved only soreness, redness, or swelling in the immediate vicinity of the vaccination site or temperature of less than 40.5°C (105°F).
- Prematurity. The appropriate age for initiating most immunization in the prematurely born infant is the usual recommended chronologic age. Vaccine doses should not be reduced for preterm infants.
- Pregnancy of mother or other household contact. Vaccine viruses in MMR vaccine are not transmitted by vaccine recipients. Although varicella vaccine and influenza vaccine viruses have been transmitted by a healthy vaccine recipient to contacts, the frequency is rare, only mild or asymptomatic infection has been reported, and use of vaccine is not contraindicated by pregnancy of the child's mother or other household contacts.
- Recent exposure to an infectious disease.
- Breastfeeding. The only vaccine virus that has been isolated from breast milk is rubella vaccine virus. No evidence indicates that breast milk from women immunized against rubella is harmful to infants.
- A history of nonspecific allergies or relatives with allergies.
- Allergies to penicillin or any other antibiotic, except anaphylactic reactions to neomycin or streptomycin. These reactions occur rarely, and none of the vaccines licensed in the United States contains penicillin.
- Allergies to duck meat or duck feathers. No vaccine available in the United States is produced in substrates containing duck antigens.
- Family history of convulsions in persons considered for pertussis or measles vaccination.
- Family history of sudden infant death syndrome in children considered for DTaP vaccination.
- Family history of an adverse event, unrelated to immunosuppression after vaccination.
- Malnutrition.

DTaP, Diphtheria-tetanus-acellular pertussis; MMR, measles-mumps-rubella.

Modified from American Academy of Pediatrics. Active immunization. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:1–56.

with other medical interventions because in contrast to most pharmaceutical products that are administered to ill people for curative purposes, vaccines usually are given to healthy people to prevent disease acquisition. Public tolerance of adverse reactions due to products given to healthy people, especially healthy infants, is substantially lower than that to products administered to people who are already ill.

The lower tolerance of risk for vaccines necessitates investigating possible causes of rare adverse events after administration of vaccinations more aggressively than would be acceptable for other pharmaceutical products. Because vaccination is such a common event, any health problem that occurs after immunization can be attributed to the vaccine. Health effects reported as being associated with vaccines may be true adverse reactions or may be associated with vaccination only by coincidence. Because a temporal relationship alone does not prove causation, cause-and-effect relationships often are impossible to establish. Epidemiologic and related studies must be performed to ascertain the incidence and nature of adverse reactions to vaccines. The studies are important in ensuring a scientific rationale for recommendations for vaccine use and optimal public and professional acceptance of vaccines.

The topic of vaccine safety became prominent during the mid-1970s with increases in the number of lawsuits filed on behalf of patients

TABLE 245.6 Recommended Immunizations for Travelers to Developing Countries

Immunizations	LENGTH OF TRAVEL		
	Brief (<2 wk)	Intermediate (2 wk–3 mo)	Long-Term Residential (>3 mo)
Review and complete age-appropriate childhood schedule	+	+	+
DTaP, poliovirus, pneumococcal, and <i>Haemophilus influenzae</i> type b vaccines may be given at 4-week intervals if necessary to complete the recommended schedule before departure. Rotavirus vaccine has maximum ages for the first and last doses; consideration should be given to the timing of an infant's travel so that the infant will be able to receive the vaccine series.			
Measles: Infants 6–11 mo of age should receive 1 dose of MMR vaccine before departure. Two additional doses are given if younger than 12 mo of age at first dose.			
Varicella			
Hepatitis A ^a			
Hepatitis B ^b			
Vaccines against the following diseases should be considered depending on the geographic area and circumstances of the visit:			
Japanese encephalitis ^c	±	±	+
Meningococcal disease ^d	±	±	±
Rabies ^e	±	+	+
Typhoid fever ^f	±	+	+
Yellow fever ^g	+	+	+

^aIndicated for travelers to areas with intermediate or high endemic rates of hepatitis A virus infection.

^bIf insufficient time to complete 6-month primary series, an accelerated series can be given.

^cFor regions with endemic infection. For high-risk activities in areas experiencing outbreaks, vaccine is recommended, even for brief travel.

^dRecommended for regions of Africa with endemic infection and during local epidemics and required for travel to Saudi Arabia for the Hajj.

^eIndicated for persons at high risk for animal exposure (especially dogs) and for travelers to countries with endemic infection.

^fIndicated for travelers who will consume food and liquids in areas of poor sanitation.

^gFor regions with endemic infection.

DTaP, Diphtheria-tetanus-acellular pertussis.

Modified from American Academy of Pediatrics. Immunizations in special clinical circumstances. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds.. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:101–107; Centers for Disease Control and Prevention. Health information for international travel, 2016: international travel with infants and young children. <http://wwwnc.cdc.gov/travel/yellowbook/2016/international-travel-with-infants-children/vaccine-recommendations-for-infants-children>

presumably injured by the diphtheria-tetanus-pertussis (DTP) vaccine.²⁸⁰ Legal decisions were made and damages awarded despite the lack of scientific evidence to support claims of vaccine injury.²⁸⁰ As a result of the liability, prices soared, and several manufacturers halted production. A shortage of vaccines resulted, and public health officials became concerned about the return of epidemic diseases. To reduce liability and respond to public health concerns, Congress passed the NCVIA in 1986.

The NCVIA mandates that all health care providers report certain adverse events that occur after the administration of vaccination with routinely recommended childhood vaccines. As a result, the VAERS was established by the US Food and Drug Administration (FDA) and the CDC in 1990. VAERS provides a mechanism for the collection and analysis of adverse events associated with vaccines currently licensed in the United States. Adverse events are defined as health effects occurring after immunization that may or may not be related to the vaccine. VAERS data are monitored continually to detect previously unknown adverse events or increases in known adverse events.¹⁸⁷

The gaps that exist in the scientific knowledge of rare vaccine adverse events prompted the CDC to develop the Vaccine Safety Datalink (VSD) project.¹⁸⁵ It involved forming partnerships with four large health maintenance organizations to monitor vaccine safety continually. VSD is an example of a large, linked database and includes information on more than 6 million people. The VSD project enables planned vaccine safety studies and timely investigations of hypotheses. The CDC has established an Immunization Safety Office (<http://www.cdc.gov/vaccinesafety/iso.html>) that identifies possible vaccine side effects and conducts studies to determine whether health problems are caused by vaccines.

Reference Sources

Several comprehensive sources of information about pediatric vaccines are available. The AAP publishes *The Red Book: Report of the Committee on Infectious Diseases* every 3 years. The next edition will be published in 2018. In the interval between editions, the AAP publishes recommendations in its newsletter *AAP News* and subsequently in *Pediatrics*. The ACIP issues vaccine recommendations and relevant information in *Morbidity and Mortality Weekly Report*. Manufacturers provide product information for each vaccine in the FDA-approved package inserts.

VACCINES RECOMMENDED FOR ROUTINE ADMINISTRATION

Diphtheria Toxoid

The introduction of diphtheria toxoid-containing vaccine in the 1940s led to a dramatic reduction in the incidence of diphtheria in the United States. From 1980 through 2004, 57 cases of diphtheria were reported in the United States, an average of 2 to 3 per year,⁴⁰⁵ and only five cases have been reported since 2000. A confirmed case has not been reported in the United States since 2003.³¹ However, diphtheria remains a potentially significant public health problem. Serologic surveys in the United States and England have suggested that many adults are not immune.^{219,405,449}

Although a study published in 1996 demonstrated that most adults in the United States do have protective concentrations of serum antitoxin,³²¹ data obtained from a national population-based serosurvey published in 2002 revealed that the prevalence of immunity to diphtheria, as determined by the level of diphtheria antitoxin, progressively decreased

from 91% among children 6 to 11 years of age to approximately 30% among those 60 to 69 years of age.⁴⁷² Of the reported cases with known patient age since 1980, 58% were among people 20 years of age or older and 44% were among people 40 years of age or older. Most cases have occurred in unimmunized or inadequately immunized people.

The current age distribution of cases corroborates the finding of inadequate levels of circulating antitoxin in many adults. Adequate immunization has not eliminated the potential for transmission of *Corynebacterium diphtheriae* completely because immunization does not prevent carriage of *C. diphtheriae* in the nasopharynx or on the skin.^{90,405}

C. diphtheriae requires infection with a virus to acquire the genetic information for toxin production, which is the primary mediator of disease. When isolated, strains of *C. diphtheriae* should be tested for toxin production to establish causality in clinical disease. Non-toxin-producing strains can cause an undifferentiated pharyngitis that is usually self-limited. Because the organism requires tellurite for growth, the microbiology laboratory must be alerted to the fact that diphtheria is suspected when specimens are submitted. Polymerase chain reaction (PCR) methods can help in making the diagnosis if antibiotics have been given before obtaining cultures.

C. diphtheriae is further subdivided into four biotypes: *gravis*, *intermedius*, *mitis*, and *belfanti*. All four biotypes have the potential to produce toxin. Humans are the reservoir for *C. diphtheriae* and may be asymptomatic. Transmission occurs by respiratory droplets or contaminated fomites. Asymptomatic carriers and those with disease can shed the organism for weeks after infection. Shedding is terminated within 48 hours of initiating appropriate antimicrobial therapy.

As a result of inadequate immunity in adults, infants, and children, an epidemic of diphtheria occurred in the 1990s throughout the former Soviet Union, including Russia, Ukraine, and the central Asian republics. Case-fatality rates ranged from 3% to 23%.^{285,334} Diphtheria continues to be a significant cause of morbidity and mortality in developing countries,²⁸⁵ and it therefore remains a source of possible exposure during travel to endemic countries. Because humans are the only known reservoir for *C. diphtheriae*, universal immunization with a diphtheria toxoid-containing vaccine is the only effective control measure.

Preparations

Diphtheria toxoid is produced by growing toxigenic *C. diphtheriae* in liquid medium. The filtrate is incubated with formaldehyde to convert toxin to toxoid and then is adsorbed onto an aluminum salt adjuvant.

Diphtheria toxoid is available in combination with DTaP for routine immunization of infants and children younger than 7 years and for adolescents and adults 11 to 64 years of age as a single booster (Tdap). Two brands of Tdap are available: Boostrix (approved for people ≥ 10 years of age) and Adacel (approved for people 11 to 64 years of age). DTaP and Tdap vaccines do not contain thimerosal as a preservative. Diphtheria toxoid also is available as a DTaP-inactivated poliovirus (IPV)-hepatitis B combination, a DTaP-inactivated poliovirus (IPV)-Hib conjugate combination, and in combination with tetanus toxoid (i.e., DT and Td) for use when pertussis vaccination is contraindicated. No diphtheria-only vaccine is available. Hib, pneumococcal, and meningococcal conjugate vaccines containing diphtheria toxoid or CRM197 protein, a nontoxic variant of diphtheria toxin used as an adjuvant, are not substitutes for diphtheria toxoid immunization.³¹

Pediatric formulations (i.e., DT and DTaP) contain an amount of tetanus toxoid similar to adult Td, but they contain three to four times as much diphtheria toxoid. The concentration of diphtheria toxoid (D) for children younger than 7 years per 0.5-mL intramuscular dose of DTaP or DT vaccine is 6.7 to 25 limit of flocculation (Lf) units, depending on the vaccine manufacturer. Vaccines approved for children 7 years or older and adults (i.e., Tdap and Td) contain only a fraction of the diphtheria toxoid (d = 2–2.5 Lf) because of adverse reactions related to dose and age.^{31,90,405}

Immunogenicity

After a primary series of three properly spaced diphtheria toxoid doses in adults or four doses in infants, a protective level of antitoxin (≥ 0.1 IU

of antitoxin/mL) is reached in more than 95% of vaccinees. Diphtheria toxoid has been estimated to have a clinical efficacy rate of 97%. Immune response to diphtheria toxoid was measured after administration of each adult Tdap vaccine and compared with that elaborated after Td vaccine. Seroprotective antidiphtheria levels, defined as a titer of 0.1 IU/mL or more, and booster response rates to diphtheria were determined to be noninferior after administration of Tdap compared with Td vaccination.⁴⁰⁵

Adverse Events

Other than local reactions of pain and swelling at the site of vaccine injection, immunization does not cause significant adverse events. These local reactions have been attributed to hypersensitivity reactions in response to the pertussis component and are not a contraindication for administration of further vaccination if otherwise indicated.

Regarding adverse reactions reported after administration of Tdap, vaccination with Boostrix was associated with a statistically higher rate of moderate to severe headache compared with Td, and vaccination with Adacel was associated with higher rates of mild injection site pain and low-grade fever compared with the Td vaccine. No serious adverse events have been reported for Boostrix. There have been two reports of serious adverse events, both characterized as neuropathic reactions, in adults, possibly related to having received Adacel (none reported in adolescents), and in both cases, symptoms resolved completely within several days.⁹⁰

When administered in the third trimester of pregnancy as recommended by the ACIP, there has been no association with increases in poor birth outcomes or maternal adverse events.^{90,243,488,625}

Indications

Primary immunization consists of five doses of diphtheria toxoid, provided as DTaP or as DT if pertussis is contraindicated.^{31,90,405} The first three doses are administered routinely to children who are 2, 4, and 6 months of age. A fourth dose is administered 6 to 12 months after the third dose, between 12 to 18 months of age, to maintain adequate antibody concentrations for the ensuing preschool years. For those not immunized in infancy, the initial dose is followed by two doses given 2 and 8 to 14 months later. A single booster dose given when the child is 4 to 6 years of age (before school entry) is indicated unless the preceding dose was given after the fourth birthday. Interruption of the recommended schedule or delay in administering subsequent doses during primary immunization does not reduce immunity or necessitate restarting the series.

In 2005, the FDA licensed two vaccines containing tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis antigens (i.e., Tdap) for routine use in adolescents and adults. Tdap is recommended only for a single dose across all age groups, including as a one-time-only substitute for the next scheduled or recommended Td booster in individuals who previously completed their primary vaccination series with DTP or DTaP. The preferred age for Tdap vaccination is 11 to 12 years. Adolescents 11 to 18 years of age who completed their primary series with DTP or DTaP are encouraged to receive Tdap. Tdap may be given without regard to prior immunization history (e.g., those who received Td less than 10 years earlier) to a patient for whom pertussis immunization is indicated.

Although longer intervals between Td and Tdap could decrease the occurrence of local reactions, the benefits of protection against pertussis outweigh the potential risk for adverse events.¹⁷⁰ Every 10 years thereafter, a tetanus booster should be provided by Td vaccine. Adolescents between the ages of 11 and 18 years who have never been vaccinated against tetanus, diphtheria, or pertussis initially should receive Tdap followed by Td for the subsequent two doses at 4 weeks or more and 6 to 12 months after that.

No pertussis-containing vaccine has been FDA approved for children between the ages of 7 and 10 years. If pertussis vaccine is not contraindicated, children 7 through 10 years of age who are not fully vaccinated (i.e., have not received five doses of DTaP or four doses of DTaP if the fourth dose was administered on or after the fourth birthday) should receive a single dose of Tdap to provide protection against pertussis. If additional doses of tetanus and diphtheria toxoid-containing vaccines

are needed for children 7 through 10 years of age after Tdap vaccine is substituted as the first dose, Td vaccine should be provided for the subsequent two doses at 4 weeks or more and 6 to 12 months after that if indicated for the catch-up series.^{31,171} Tdap is recommended in this age group because of its reduced antigen content compared with DTaP, resulting in reduced reactogenicity.¹⁷¹ Pregnant woman should receive Tdap early in the third trimester of each pregnancy.¹⁷¹

After exposure to a case of strongly suspected or proven diphtheria, asymptomatic, previously immunized people should receive a booster of an age-appropriate diphtheria toxoid-containing vaccine if they have not received a booster dose of a diphtheria toxoid-containing vaccine within 5 years. For people 10 years or older, Tdap is preferred over Td if a pertussis booster vaccine was not previously received.³¹ If not previously immunized, carriers should receive age-appropriate diphtheria toxoid-containing vaccine (i.e., DTaP [or DT], Tdap, or Td) as soon as identified and should complete the entire series. Patients recovering from diphtheria infection should be immunized because infection does not confer immunity.

Precautions and Contraindications

The only contraindication to diphtheria toxoid is a history of severe hypersensitivity developing after receipt of a previous vaccine dose. Vaccination with diphtheria or tetanus toxoid is not associated with an increased risk of convulsions. Local reactions alone do not preclude continued use.

Haemophilus influenzae Type b Vaccine

Before the introduction of routine infant and childhood vaccination against Hib in 1985, this pathogen was the major cause of invasive bacterial infections in young children in the United States. It was the most common cause of bacterial meningitis and epiglottitis and a significant cause of septic arthritis, osteomyelitis, septicemia, occult febrile bacteremia, pneumonia, pericarditis, and cellulitis in children younger than 5 years, in whom it caused an estimated 12,000 cases of meningitis and 8000 additional cases of invasive Hib disease annually.¹⁹⁸ The cumulative risk for Hib disease was approximately one among every 200 US children in the first 5 years of life, with the peak incidence of Hib meningitis occurring among infants between 6 and 12 months of age. In high-risk populations, such as American Indians and Alaska Natives, rates of disease in the absence of immunizations were higher, and a greater proportion of cases of meningitis occurred early in the first year of life than in low-risk populations.^{198,343,680} Although rates of Hib disease among these vulnerable populations have decreased in the postvaccine era, they remain 8 to 10 times higher compared with white and black children younger than 5 years.⁸⁹

In 2000, before the widespread introduction of Hib vaccines in resource-poor countries, the WHO estimated that at least 8 million cases of serious disease in children and approximately 371,000 deaths were attributable to Hib annually.⁶⁹⁹ As of 2014, 192 of the 193 WHO member states (99.5%) had adopted conjugated Hib vaccines in their routine immunization programs. As a consequence, invasive Hib disease has been virtually eliminated in many industrialized countries, and its incidence has declined by more than 90% in resource-poor countries with effective national immunization programs. However, the WHO estimates that only 56% of the eligible population globally receives three doses of Hib vaccine, and coverage rates are as low as 21% in the western Pacific.

Hib remains the most common cause of nonepidemic bacterial meningitis among unvaccinated children younger than 1 year. The mortality rate for Hib meningitis treated with appropriate antibiotics is approximately 4%, and 15% to 30% of survivors have hearing impairment or severe permanent neurologic sequelae.⁸⁹

Because most cases of Hib disease occur in infancy, vaccines that induce protection before the age of 6 months are necessary for effective control of Hib disease. The Hib polysaccharide capsule is the major virulence factor, and bactericidal antibodies directed against the polysaccharide antigens are protective. Capsular type b is responsible for more than 90% of systemic *H. influenzae* infections. However, purified polysaccharide vaccines are poor immunogens and children’s T-lymphocyte-independent immunoglobulin M (IgM) response is largely

ineffective, particularly in children younger than 18 months who lack immunologic memory. Covalent linkage of the purified capsular polysaccharide, polyribosylribitol phosphate (PRP), to a protein carrier creates a conjugate glycoprotein that is T-lymphocyte dependent and elicits protective antibody in infants and young children and significantly greater concentrations of circulating anti-PRP at all ages than does the unconjugated polysaccharide. T-cell-dependent antigens involve helper T-lymphocyte activation of a B-cell humoral antibody response. T-cell-dependent antigens also are able to prime a booster response and induce immunologic memory (i.e., anamnestic response).

The introduction of Hib conjugate vaccines in the United States, first in children at least 18 months of age in 1987 and for routine infant immunization in 1990, dramatically decreased the incidence of meningitis and bacteremia caused by Hib. As of 2000, the incidence of invasive Hib disease in the United States had decreased by 99% since the prevaccine era, with an incidence rate of less than one case per 100,000.¹⁴³ During 2000 through 2012, the average annual incidence of invasive disease in young children was lower than the Healthy People 2020 goal of 0.27 case per 100,000 children.⁸⁹ The remarkably rapid reduction in incidence of disease was partly the result of the ability of the vaccine to reduce asymptomatic oropharyngeal colonization in vaccinated children that also had the indirect effect of reducing exposure and infection in those not immunized (i.e., community or herd immunity).^{63,338} Colonization rates have declined from up to 7% in the prevaccine era to less than 1% in the vaccine era.

Preparations

Three single-antigen Hib conjugate vaccine products and two combination vaccine products that contain Hib conjugate are available in the United States. All Hib vaccines contain polyribosylribitol phosphate (PRP), the organism’s polysaccharide capsular antigen. Three licensed single-antigen Hib conjugate vaccines—PRP-OMP (PedvaxHIB, Merck), PRP-T (ActHIB, Sanofi Pasteur), and PRP-T (Hiberix, GlaxoSmithKline)—are approved for use in early infancy (Table 245.7).

Each conjugate vaccine is chemically and immunologically unique. PRP preparations are composed of the type b PRP antigen conjugated to a protein, but they have different protein carriers, sizes of the saccharide component, and chemical linkages. The carrier proteins for PRP-OMP and PRP-T are an outer membrane protein from *Neisseria meningitidis* and tetanus toxoid, respectively. Since July 2000, the entire Hib vaccine supply for the United States has been thimerosal free. The dose of each Hib conjugate vaccine is 0.5 mL and given intramuscularly.

Two licensed combination vaccines containing Hib are available in the United States: DTaP/IPV/PRP-T (Pentacel, Sanofi Pasteur), which is approved for immunization at 2, 4, 6, and 15 to 18 months of age, and MenCY/PRP-T (MenHibrix, GlaxoSmithKline), a combination conjugate vaccine approved in 2012 for children 6 weeks to 18 months of age to prevent meningococcal serogroups C and Y and Hib. Use of DTaP/PRP-T (TriHIBit, Sanofi Pasteur) was discontinued in 2011, and PRP-OMP/Hep B (Comvax, Merck) was discontinued in 2014.

TABLE 245.7 *Haemophilus influenzae* Type b Vaccine Schedules

VACCINE		AGE AT VACCINATION			
Type	Trade Name	2 mo	4 mo	6 mo	12–15 mo
PRP-T	ActHIB	X (1st)	X (2nd)	X (3rd)	X
	Pentacel ^a	X (1st)	X (2nd)	X (3rd)	X
	Hiberix	X (1st)	X (2nd)	X (3rd)	X
	MenHibrix ^b	X (1st)	X (2nd)	X (3rd)	X
PRP-OMP	PedvaxHIB	X (1st)	X (2nd)	—	X

^aCombination vaccine with DTaP/IPV + PRP-T.

^bCombination vaccine with MenCY + PRP-T.

PRP-OMP, Polyribosylribitol phosphate conjugated to the outer membrane protein complex from *Neisseria meningitidis*; PRP-T, polyribosylribitol phosphate conjugated to tetanus toxoid.

Immunogenicity and Efficacy

Placebo-controlled field trials of Hib conjugate vaccines in infants in the United States demonstrated almost 100% protection and provided the basis for the initial approval of these vaccines for use in this country. In a Navajo population of infants at high risk for Hib disease who were vaccinated at 2 and 4 months of age with PRP-OMP or placebo, vaccine efficacy was 100% at 1 year of age and 93% in total.⁵⁷⁷ Licensure of PRP-T was based on immunogenicity in a three-dose schedule that was comparable to that of the other two products. A clinical trial in Great Britain found the efficacy of PRP-T comparable to that of PRP-OMP.^{84,649}

Although the data are limited, some evidence suggests that administration of the first dose of the Hib vaccine before the child reaches the age of 6 weeks may result in immunologic tolerance to the Hib antigen and reduce the immune response to subsequent doses.⁴⁷³ Therefore, Hib vaccines, including combination vaccines that contain Hib conjugate, should not be given to an infant younger than 6 weeks.

Long-term protection induced by invasive Hib disease in unvaccinated children is associated with an anti-PRP antibody concentration of greater than 0.15 µg/mL, whereas concentrations greater than 1.0 µg/mL are considered to be markers of long-term protective immunity in vaccinated children.⁸⁹ Children who have invasive Hib infection before 24 months of age may remain at risk for another Hib infection, and they should be immunized according to the age-appropriate schedule for unimmunized children.³² Children who develop invasive disease despite two to three Hib vaccines and those with recurrent invasive Hib warrant an immunologic evaluation. Nontypeable *H. influenzae* lacks a polysaccharide capsule that renders the Hib vaccine ineffective against this cause of acute otitis media (AOM), acute sinusitis, bronchitis, and community-acquired pneumonia.

Adverse Events

Hib vaccines are well tolerated. Local reactions occur in approximately 25% of recipients but typically are mild and last less than 24 hours.^{232,680} Systemic reactions such as fever and irritability are infrequent occurrences. When conjugate vaccines are administered concurrently with DTaP vaccine, the incidence of systemic reactions is similar to that observed when only DTaP is given.²³²

Indications

Routine vaccination against Hib disease is recommended for all children beginning at approximately 2 months of age.^{32,89} Two or three doses, depending on the product, given at 2-month intervals (optimal) are indicated by the time that the child is 6 months of age. PedvaxHIB is given as a two-dose primary series at 2 and 4 months, whereas ActHIB, Hiberix, Pentacel, and MenHibRix are approved for immunization at 2, 4, 6, and 15 to 18 months of age (see Table 245.7). The recommended age to initiate the primary series is 2 months, with a minimum age of 6 weeks. The minimum interval between doses is 4 weeks, with at least 8 weeks separating the last dose in the primary series and the booster.

Excellent immune responses have been achieved when vaccines from different manufacturers have been interchanged in the primary series.^{53,77,312} PRP-T and PRP-OMP are considered interchangeable for primary and booster vaccinations. If more than a single brand of vaccine is used, the child should receive a three-dose primary series. A final dose of any product, irrespective of the previous vaccines received, is acceptable when the child is 12 to 15 months of age for completion of the Hib vaccine immunization schedule. When feasible, the conjugate vaccine product used for the first dose should be used for subsequent doses in children younger than 12 months.

For American Indian and Alaska Natives, PRP-OMP is the preferred vaccine for the primary series doses. Hib meningitis incidence peaks at a younger age among American Indian and Alaska Native infants.^{218,608} PRP-OMP vaccine produces a protective antibody response after the first dose and provides early protection that American Indian and Alaska Native infants particularly need.^{20,232,230}

For children in whom immunization for Hib infection has not been initiated by the time that they reach 7 months of age, the recommended schedules depend on the child's age and the choice of conjugate vaccine.^{32,89} Previously unimmunized children between 15 and 59 months

should be immunized with at least a single dose of any licensed conjugate Hib vaccine. For previously unimmunized children 5 years or older, immunization is indicated only if they have an underlying condition predisposing to Hib disease, such as anatomic or functional asplenia, sickle cell disease, immunoglobulin deficiency and immunoglobulin G2 subclass deficiency, early component complement deficiencies, and HIV infection or if they are recipients of hematopoietic stem cell transplants or are immunosuppressed because of chemotherapy or radiation therapy. More than one dose may be recommended for this population.^{32,89}

Precautions and Contraindications

Adverse reactions to Hib-containing monovalent vaccines are uncommon, usually mild, and usually resolve within 12 to 24 hours.^{232,230,282,352} Rates of adverse reactions to Hib combination vaccines are similar to those observed with separately administered vaccines.^{79,319,493} More complete information about adverse reactions to a specific vaccine is available in the package insert for each vaccine.

Vaccination with a Hib-containing vaccine is contraindicated in infants younger than 6 weeks. Vaccination with a Hib-containing vaccine is contraindicated for people known to have a severe allergic reaction to any component of the vaccine. The tip caps of the Hiberix prefilled syringes can contain natural rubber latex, and the vial stoppers for Comvax, ActHib, and PedvaxHIB contain natural rubber latex, which can cause allergic reactions in people who are latex sensitive. Vaccination with these vaccines is therefore contraindicated for those known to have a severe allergic reaction to dry natural rubber latex. The vial stoppers for Pentacel and MenHibRix do not contain latex.

As with all pertussis-containing vaccines, benefits and risk should be considered before administering Pentacel to those with a history of fever higher than 40.5°C, hypotonic-hyporesponsive episode, persistent inconsolable crying lasting 3 or more hours within 48 hours after receipt of a pertussis-containing vaccine, or seizures within 3 days of receiving a pertussis-containing vaccine.

Hib monovalent and combination conjugate vaccines are inactivated vaccines and can be administered to people with immunocompromising conditions. However, immunologic response to the vaccine may be suboptimal.⁴⁰⁸

Hepatitis A Vaccine

The occurrence of hepatitis A is highest in developing countries and reflects the primary route of transmission: fecal-oral, person-to-person spread. In the United States, before vaccine became available, hepatitis A was a common infection that caused substantial morbidity with significant associated costs.^{151,400} In 1995, the hepatitis A vaccine was licensed by the FDA, and during the decades that followed, acute hepatitis A infection in the United States dramatically declined, from 31,032 reported infections in 1995 to an all-time low of 1398 in 2011.^{270,494} In 2012 and 2013, however, the first increases in cases occurred since 1995, with 1562 and 1781 reported cases, respectively.⁴⁹⁴

In the prevaccine era, the incidence of hepatitis A varied considerably among different populations.^{270,619} A shift occurred in the epidemiology of hepatitis A in the United States after the introduction of hepatitis A vaccine. Disease in the United States most commonly occurred in children 5 to 14 years of age.²⁷⁰ After vaccines were licensed, rates of infection among children declined more rapidly than did rates among adults, resulting in similar rates among all age groups. Historically, rates of infection were highest among Alaska Natives and American Indians, and most cases occurred in a small number of states and counties in the western and southwestern regions of the country. During the decades after vaccine licensure, we have seen near-elimination of age-specific, racial, and geographic disparities.^{270,494}

Individuals at risk for hepatitis A infections include close contacts of people infected with hepatitis A virus (HAV), travelers to developing countries, those who engage in homosexual and bisexual activity, and injecting drug users. However, in approximately 50% of reported cases, no risk factor is identified.³³ These infections likely are attributable to fecal-oral spread from asymptomatic contacts. Because children frequently have asymptomatic infections and can shed virus for prolonged periods, they play an important role in transmission of HAV. Children and

infants shed virus for longer periods than adults do, up to several months after the onset of clinical illness. In one study involving adults without an identified source of infection, 52% of their households included a child younger than 6 years.²⁷⁰

It has long been recognized that the control and ultimate elimination of hepatitis A by active immunization could best be achieved through universal childhood immunization.⁶⁵¹ However, it was not until 2005 that hepatitis A vaccine was licensed for use in children from 12 to 23 months of age. Before then, it had been restricted to children older than 2 years and consequently could not be incorporated readily into routine infant vaccinations. In May 2006, the ACIP recommended including hepatitis A vaccine in the routine infant immunization schedule.²⁷⁰

Before vaccine was available, community-wide outbreaks, recurring every 3 to 10 years in high-risk communities, accounted for much of the occurrence of hepatitis A infection and disease. Outbreaks among children attending childcare and the staff are common occurrences and have been associated with community outbreaks.³²⁶ However, the prevalence of hepatitis A infection among childcare center staff and the children and adolescents who previously attended is not increased, a finding suggesting that infections within childcare settings most commonly reflect transmission within the community that extends to these settings.³²⁶ Transmission of HAV also can occur in institutions for the developmentally disabled and in neonatal intensive care units. Transmissions from hospitalized patients to health care professionals have been reported.³³

In addition to direct person-to-person transmission, infection can be acquired by the ingestion of contaminated water or food, especially that imported from endemic countries. An outbreak in 2013 from contaminated pomegranate seeds, which were imported to the United States from Turkey, infected 165 people across 10 states; 42% were hospitalized, three developed fulminate hepatitis, and one required liver transplantation.⁴⁹⁴

Preparations

Inactivated and attenuated HAV vaccines have been developed.²³⁹ However, only inactivated vaccines are licensed in the United States. Inactivated HAV vaccine is prepared by methods similar to those used for inactivated poliomyelitis vaccine. Virus is propagated in human diploid fibroblast cell cultures, formalin inactivated, and adsorbed to aluminum hydroxide adjuvant. Two inactivated HAV vaccines are licensed in the United States: Havrix (SmithKline Beecham Biologicals) and Vaqta (Merck & Co.). Vaqta and Havrix have two formulations, an adult and a pediatric product with different antigen content (Table 245.8). The pediatric formulation is indicated for people 12 months to 18 years of age. The vaccines can be used interchangeably.⁹⁵

Limited data indicate that hepatitis A vaccine may be administered simultaneously with other vaccinations.³³ A combination HAV and

hepatitis B vaccine (Twinrix) is licensed in the United States for people 18 years and older. All HAV-containing vaccines are administered intramuscularly.

Immunogenicity and Efficacy

Inactivated hepatitis A vaccine is highly immunogenic. After receiving a single dose, 95% of children and most adults seroconvert within 1 month.^{33,270} After receipt of a second dose in children, seroconversion approximates 100%. Hepatitis A vaccine is immunogenic in children younger than 2 years old who do not have passively acquired maternal antibody.^{536,643} In two large clinical trials of inactivated hepatitis A vaccine in children older than 2 years, the protective efficacy rate was greater than 90%.^{358,682} In a double-blind, placebo-controlled, randomized study in Thailand involving approximately 34,000 vaccinees, the protective efficacy rate against clinical hepatitis A was 94% after administration of two doses given 1 month apart; it was 100% after subsequent administration of a 12-month booster dose.³⁵⁸

Vaccination has been effective in controlling outbreaks in communities with high rates of disease.²⁷⁰ For example, in a New York State community in which HAV was highly endemic among children, a single dose of vaccine was 100% effective beginning 3 weeks after immunization in preventing symptomatic disease.⁶⁸² Moreover, observations from countries where routine hepatitis A vaccination of infants or children has been implemented suggest a strong herd immunity effect.^{221,240} The duration of protection after vaccination is likely to be prolonged. Protective antibody levels of anti-HAV were observed in 99% of children evaluated 5 to 6 years after receiving Vaqta.⁶⁸¹ Kinetic models of antibody decline indicate that protective levels of antibody could exist for more than 25 years in adults and up to 20 years in children.^{650,652} No data are available to determine whether and when children will need a hepatitis A booster vaccine. In an ongoing study designed to address the need for a booster dose, no cases of hepatitis A among children 9 years after initial vaccination have been reported.⁶⁸³

Reduced vaccine immunogenicity has been observed in infants with passively acquired anti-hepatitis A antibody who are administered hepatitis A vaccines.^{221,428,433} Studies demonstrated that despite lower antibody levels in infants born to anti-hepatitis A–positive mothers, most infants with passively acquired antibody had an anamnestic response to a booster dose 1 to 6 years later.^{221,269,380} In most infants, maternally acquired anti-hepatitis A antibody declines to undetectable levels by the time the child reaches 12 months of age.⁴³² Hepatitis A vaccine is highly immunogenic for all infants when administered when they are older than 1 year, irrespective of maternal antibody status.^{72,221}

Concurrent administration of immune globulin and vaccine inhibits the peak serum antibody concentration achieved but not the rate of seroconversion.⁶⁶⁶ Because antibody concentrations reach much higher than protective levels, this inhibition is not considered clinically significant and supports passive-active immunoprophylaxis when indicated.

TABLE 245.8 Recommended Doses and Schedules for Inactivated Hepatitis A Vaccines

Age (y)	Vaccine Trade Name	Hepatitis A Antigen Dose	Volume per Dose (mL)	No. of Doses	Schedule
1–18	Havrix	720 ELU	0.5	2	Initial and 6≥12 mo later
1–18	Vaqta	25 U ^a	0.5	2	Initial and 6≥18 mo later
≥19	Havrix	1440 ELU	1.0	2	Initial and 6≥12 mo later
≥19	Vaqta	50 U ^b	1.0	2	Initial and 6≥18 mo later
≥18	Twinrix ^c	720 ELU	1.0	3 or 4	Initial, 1 and 6 mo later or Initial, 7 days and 21–30 d, followed by a dose at 12 mo

^aAntigen units; each unit is equivalent to 1 µg of viral protein.

^bA combination of hepatitis B (Engerix-B, 20 µg) and hepatitis A (Havrix, 720 ELU) vaccine.

^cTwinrix is licensed for use in people ≥18 years in 3-dose and 4-dose schedules.

ELU, Enzyme-linked immunosorbent assay units.

Modified from American Academy of Pediatrics. Hepatitis A. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:391–9.

Adverse Events

Except for rare reports of anaphylaxis and anaphylactoid reaction in adults in Europe and Asia, serious reactions to inactivated HAV vaccine have not been reported.^{269,380} Pain, tenderness, and infection at the injection site can occur.³⁵⁸

Indications

HAV immunization is recommended routinely for children 12 through 23 months of age, for people who are at increased risk for infection, for those who are at increased risk for severe manifestations of hepatitis A if infected, and for anyone who wants to obtain immunity.^{22,33,151,156,270}

All children in the United States should receive hepatitis A vaccine routinely according to the licensed two-dose schedule, with the initial dose administered at 1 year of age (i.e., 12 to 23 months) and the second dose 6 to 12 months later. Children who are not immunized by 2 years of age can be immunized at subsequent visits.

Hepatitis A vaccination is recommended routinely for the following people who are at increased risk for infection^{22,33,270}:

- All susceptible people traveling to or working in countries that have a high or intermediate hepatitis A endemicity should be vaccinated or receive immune globulin before departure.¹⁵¹ HAV vaccine at the age-appropriate dose is preferred to immune globulin. The first dose of HAV vaccine should be administered as soon as travel is considered. One dose of single-antigen vaccine administered at any time before departure can provide adequate protection for most healthy people. Travelers who are younger than 12 months should receive a single dose of immune globulin (0.02 mL/kg), which provides effective protection for up to 3 months; 0.06 mL/kg for travel provides protection up to 6 months.
- Susceptible household members and other close personal contacts of international adoptees newly arriving from countries with high or intermediate hepatitis A endemicity should be vaccinated.^{27,156} Data from a study conducted at three adoption clinics in the United States indicate that 1% to 6% of newly arrived international adoptees have acute HAV infection. The risk of HAV infection among close personal contacts of international adoptees is estimated at 106 (range, 90–819) per 100,000 household contacts of international adoptees within the first 60 days after their arrival in the United States. HAV vaccine should be administered to all previously unvaccinated people who anticipate close personal contact (e.g., household contact, regular babysitters) with an international adoptee from a country with high or intermediate endemicity during the first 60 days after arrival of the adoptee in the United States. The first dose of the two-dose HAV vaccine series should be administered as soon as adoption is planned, ideally two or more weeks before the arrival of the adoptee.
- Male adolescents and adults who have sex with men should be immunized. Outbreaks of hepatitis A among men who have sex with men have been reported often, including in urban areas in the United States, Canada, and Australia.

- Adolescent and adult users of injection and noninjection drugs should be vaccinated. Periodic outbreaks among injection and noninjection drug users have been reported in many parts of the United States and in Europe.
- Susceptible patients with chronic clotting disorders who receive clotting factor concentrates should be immunized. Reported outbreaks of hepatitis A in patients with hemophilia receiving solvent-detergent-treated factor VIII and factor IX concentrates were identified during the 1990s, primarily in Europe, although one case was reported in the United States.
- People at risk for occupational exposure (e.g., handlers of HAV-infected primates, people working with HAV in a research laboratory setting) should be immunized. Outbreaks of hepatitis A have been reported among people working with nonhuman primates that were born in the wild rather than those born and raised in captivity.
- People with chronic liver disease are at increased risk for fulminant hepatitis A. Susceptible patients who are awaiting or have received liver transplants should be immunized.

Although the ACIP guidelines do not recommend routine vaccination of food handlers, vaccination of these workers should be considered in areas where state and local health authorities or private employers determine that vaccination is cost-effective.

Postexposure Prophylaxis

People who have been exposed to HAV but have not received HAV vaccine should have one dose of single-antigen HAV vaccine or immune globulin as soon as possible.¹⁵¹ Table 245.9 provides prophylaxis guidance and dosages. The efficacy of immune globulin or vaccine for postexposure prophylaxis when administered more than 2 weeks after exposure has not been established. Information about the relative efficacy of vaccine compared with immune globulin after exposure is limited, and no data are available for people older than 40 years or those with underlying medical conditions.

All previously unimmunized people with close personal contact with a person with serologically confirmed HAV infection, such as household and sexual contacts, should receive vaccine or immune globulin within 2 weeks after the most recent exposure. Serologic testing of contacts is not recommended because testing adds unnecessary cost and may delay administration of postexposure prophylaxis.

Outbreaks of HAV infection at childcare centers have been recognized since the 1970s, but their frequency has decreased as HAV immunization rates for children have increased and as hepatitis A incidence among children has declined. HAV vaccine or immune globulin should be administered to all previously unimmunized staff members and attendees of childcare centers or homes if one or more cases of hepatitis A are recognized in children or staff members or cases are recognized in two or more households of center attendees. In centers that provide care only to children who do not wear diapers, vaccine or immune globulin need be given only to classroom contacts of an index-case patient.

TABLE 245.9 Recommendations for Postexposure Immunoprophylaxis of Hepatitis A Virus

Time Since Exposure	Age of Patient	Recommended Prophylaxis ^a
≤2 wk	<12 mo	IGIM, 0.02 mL/kg
	12 mo–40 y	HAV vaccine
	≥41 y	IGIM, 0.02 mL/kg but HAV vaccine can be used if IGIM is unavailable
	People of any age who are immunocompromised, have chronic liver disease, or a contraindication to vaccination	IGIM, 0.02 mL/kg
≥2 wk	<12 mo	No prophylaxis
	≥12 mo	No prophylaxis, but HAV vaccine may be indicated for ongoing exposure

^aDosage and schedule of HAV vaccine as recommended according to age in Table 245.8.

HAV, Hepatitis A virus; IGIM, immune globulin intramuscular.

Modified from American Academy of Pediatrics. Hepatitis A. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015: 391–399.

When an outbreak occurs (i.e., hepatitis A cases identified in two or more families), vaccine or immune globulin also should be considered for members of households that have children (i.e., center attendees) in diapers. Children and adults with hepatitis A should be excluded from the center until 1 week after onset of illness, until the postexposure prophylaxis program has been completed in the center, or until directed by the health department. Although precise data concerning the onset of protection after postexposure prophylaxis are not available, allowing prophylaxis recipients to return to the childcare center setting immediately after receipt of the vaccine or immune globulin dose seems reasonable.

Schoolroom exposure usually does not pose an appreciable risk for infection, and postexposure prophylaxis is not indicated when a single case occurs and the source of infection is outside the school. However, HAV vaccine or immune globulin can be used for unimmunized people who have close contact with the index patient if transmission within the school setting is documented.

Usually, health care–associated HAV in hospital personnel has occurred through spread from patients with acute HAV infection for whom the diagnosis was not recognized. Careful hygienic practices should be emphasized when a patient with jaundice or known or suspected hepatitis A is admitted to the hospital. When outbreaks occur, HAV vaccine or immune globulin is recommended for people in close contact with infected patients. There is no recommendation for routine preexposure use of HAV vaccine for hospital personnel.

If a food handler is diagnosed with hepatitis A, HAV vaccine or immune globulin should be provided to other food handlers at the same establishment. Food handlers with acute HAV infection should be excluded for 1 week after the onset of illness. Because common-source transmission to patrons is unlikely, postexposure prophylaxis with HAV vaccine or immune globulin typically is not indicated but may be considered if the food handler directly handled food during the time when he or she likely was infectious and had diarrhea or poor hygiene practices and if prophylaxis can be provided within 2 weeks of exposure. Routine HAV immunization of food handlers is not recommended.

Precautions and Contraindications

Hepatitis A vaccine should not be administered to people with a hypersensitivity reaction to any of the vaccine components, such as alum or, in the case of Havrix, phenoxyethanol.¹⁵ Safety data for pregnant women are not available, but the risk is considered to be low or nonexistent because the vaccine contains inactivated, purified viral proteins.

Hepatitis B Vaccine

Hepatitis B virus (HBV) infection is a leading cause of acute hepatitis and a major public health problem of global importance. Its incidence is especially high in many Asian and African countries. Individuals with chronic infection are at risk for chronic hepatitis, cirrhosis, and primary hepatocellular carcinoma. Rates of new infection are highest among adults, but chronic infection is more likely to occur in individuals infected as infants or children. They are at increased risk for chronic and malignant liver disease, and as chronic carriers, they serve as the reservoir for transmission of HBV.

The initial strategies for prevention of hepatitis B through vaccination reflect the various epidemiologic patterns of HBV infection in different areas of the world.¹¹⁶ In the United States, for example, infection is of comparatively low endemicity and occurs primarily in adolescents and adults. The risk of infection, however, is much greater in certain populations. Examples include those born and living in areas or among groups in which HBV is highly endemic and those with lifestyles predisposing to the acquisition of HBV, such as male homosexual activity, intravenous drug abuse, and promiscuous heterosexual activity.¹¹ In geographic areas in which HBV infection is highly endemic, infection usually is acquired at birth or during childhood, a pattern prompting the recommendation for universal vaccination of infants. Many countries have adopted hepatitis B vaccine into their national campaigns, and children recently immigrated to the United States from endemic areas confirm this trend, with higher levels of neutralizing antibodies found in newer immigrants.⁷⁰⁹

In 1991, the CDC initiated a comprehensive hepatitis B vaccination strategy to eliminate transmission of HBV in the United States.¹¹⁶ Critical

elements of this strategy included preventing perinatal transmission of HBV by identifying and providing immunoprophylaxis to infants of hepatitis B virus surface antigen (HBsAg)–positive mothers and universal hepatitis B vaccination of infants to interrupt transmission and prevent future infection. This approach provided effective programs for routine childhood immunization, protection without any need to identify specific risk factors, and protection before significant exposure occurred. The positive effects of universal infant immunization had been observed in Taiwan, where the strategy of universal infant immunization already was being used. In Taiwan, the overall prevalence rate of HBV for children 1 to 10 years of age decreased from 9.8% in 1984 to 1.3% in 1994.¹⁸²

In 1994, the ACIP expanded the recommendations to include previously unvaccinated children 11 to 12 years old.¹²⁴ In October 1997, these recommendations were expanded to include all unvaccinated children from birth to 18 years old and made hepatitis B vaccine available through the Vaccines for Children (VFC) program for those from birth to 18 years of age who were eligible for the program.¹³⁵ The goal of the 1997 recommendations was to increase access to hepatitis B vaccine by encouraging the vaccination of previously unvaccinated children and adolescents when they were seen for routine medical visits.¹⁵ Expansion of the recommended age group for receiving vaccination and for VFC eligibility simplified previous recommendations and eligibility criteria for receiving HBV vaccine. The other ACIP priorities for giving hepatitis B vaccination to children remained unchanged and included the following groups: all infants; children in populations at high risk for HBV infection, such as Alaska Natives, Pacific Islanders, and children who reside in households of first-generation immigrants from countries where HBV infection is moderately or highly endemic; previously unvaccinated children 11 to 12 years of age; and older adolescents and adults in defined at-risk groups.^{124,116}

Between 1990 and 2004, the incidence of HBV infection in the United States declined by 75%. The decline was greatest among children and adolescents. Coincident with the decline in HBV incidence, vaccine coverage for children 19 to 35 months of age increased from 16% to 92% from 1991 to 2004.¹⁴⁷ Among adolescents 13 to 15 years old, vaccine coverage increased from 0% to 74% between 1993 and 2004 according to CDC data. Since its inception in 1991, many aspects of the national immunization strategy to eliminate HBV transmission have been implemented with great success, especially the routine vaccination of all infants. Nonetheless, many challenges remain.

Despite the overall decline in hepatitis B incidence and the recommendations for routine vaccination of infants and children, increasing proportions of new HBV infections in the United States occur among adolescents and adults who have defined risk factors, including those with multiple sex partners (i.e., more than one partner during the preceding 6 months), men who have sex with men, and injecting drug users.⁴⁴¹ The primary means of preventing these infections is to identify settings such as correctional facilities, sexually transmitted disease clinics, and drug treatment centers where adolescents and adults with high-risk drug and sexual practices can be routinely accessed and vaccinated. In correctional facilities where previously unvaccinated inmates are offered HBV vaccination, 60% to 80% of inmates accepted offered vaccination.⁶⁷⁷

Although universal screening of all pregnant women has been widely adopted across the United States, fewer than half of all HBsAg-positive pregnant women are identified through prenatal screening.²⁶¹ These women with unknown HBsAg status are not screened consistently, even when they are hospitalized during labor and delivery; consequently, their infants do not receive appropriate postexposure prophylaxis.⁶³⁵ The birth dose of HBV vaccine, which can serve as a safety net for infants born to mothers for whom testing was not performed or not performed correctly, was administered to only 45% of infants born in the United States in 2004, less than the rate of 54% seen before July of 1999, when recommendations were made to suspend the birth dose of hepatitis B vaccine temporarily until a thimerosal-free vaccine became available.⁴⁴⁰

To enhance existing strategies aimed at prevention of perinatal HBV transmission, the ACIP recommended in December of 2005 that all delivery hospitals institute specific policies and procedures to improve identification of infants born to HBsAg-positive mothers and mothers

with unknown HBsAg status.⁴⁶⁴ These recommendations were made to ensure administration of appropriate postexposure prophylaxis and a birth dose of HBV vaccine to all medically stable infants. A study of prospectively collected data from 5 of 64 US-funded Perinatal Hepatitis B Prevention Programs from 2007 through 2013 found that perinatal hepatitis B virus infection occurred among 1.1% of infants, despite 94.9% of infants receiving hepatitis B vaccine and hepatitis B immune globulin within 12 hours of birth.⁵⁸³ Infants born to mothers who were younger, hepatitis B e antigen (HBeAg) positive, or who had a high viral load or received fewer than three hepatitis B vaccine doses were at greatest risk for infection.

The 2005 ACIP statement also updated recommendations to improve vaccination coverage of adolescents and children by implementing immunization record reviews for all children 11 to 12 years old and children younger than 19 years who were born in countries with high or intermediate HBV endemicity and by vaccinating all unvaccinated adolescents in settings that provide health care services to this age group.⁴⁶⁴

Preparations

Hepatitis B vaccines consisting of inactivated, purified HBsAg derived from chronic hepatitis B plasma were introduced in the early 1980s. In the late 1980s, two recombinant vaccines (Recombivax HB, Merck & Co.; Engerix-B, SmithKline Beecham Biologicals) were licensed in the United States and are available in single-antigen and combined formulations. Only the recombinant vaccines are available in the United States, but plasma-derived vaccines are widely used in other areas of the world. The recombinant vaccines contain 5 to 40 µg/mL of HBsAg protein. Pediatric formulations contain no thimerosal or only trace amounts.

Vaccine is administered intramuscularly in the anterolateral thigh or deltoid area, depending on the age and size of the recipient. Administration in the buttocks or intradermally has been associated with decreased immunogenicity and is not recommended at any age.

Immunogenicity and Efficacy

The recommended series of three doses of vaccine induces a protective antibody response in more than 95% of infants, children, adolescents, and adults younger than 40 years.^{34,464} In field trials, the efficacy rates have been 80% to 95% and usually correlate with immunogenicity. Protection against disease is virtually 100% for people who develop adequate serum antibody concentrations (anti-HBs ≥10 mIU/mL) after receiving vaccination. Adults older than 40 years and immunosuppressed people are less likely to develop protective anti-HBs concentrations.

Hepatitis B vaccine is highly immunogenic. Postvaccination serologic testing is not indicated except for infants born to HBsAg-positive women, people with ongoing occupational exposure to blood, and people with immunosuppressive conditions. Active immunization in combination with passive immunoprophylaxis with hepatitis B immune globulin (HBIG) administered within 12 to 24 hours after birth to infants born to chronically infected mothers is more than 90% effective in preventing transmission of HBV to the infant. Active postexposure vaccination without HBIG administered soon after birth has been effective in preventing perinatal transmission and is used in areas where the use of HBIG is impractical.³¹⁰

Vaccine-induced protection against symptomatic infection in a normal host is prolonged and correlates with immunologic memory, which has been demonstrated in immunized children and adults for at least 12 years after vaccination. Children immunized at birth are protected for at least 10 years. The need for routine booster doses has not been demonstrated.

Vaccine failures related to HBV variants with mutations in the S gene leading to conformational changes in the HBsAg protein, the major target for neutralizing anti-HBs antibody, have occurred in fully vaccinated children and perinatally exposed infants who received appropriate active and passive postexposure prophylaxis and in many cases had protective anti-HBs antibody levels.³⁵⁶ Although no evidence establishes that these escape mutations pose a threat to the effectiveness of current hepatitis B vaccine programs, surveillance to detect emergence of HBV variants in immunized populations is warranted.^{464,717}

Adverse Events

Other than soreness at the injection site, reactions to hepatitis B vaccine rarely occur. Postvaccination surveillance performed after licensure of the plasma-derived vaccine indicated a possible association between Guillain-Barré syndrome and receipt of the first vaccine dose, but no evidence indicates an association of Guillain-Barré syndrome with recombinant vaccine.^{464,465} Anaphylaxis has been estimated to occur in one of 600,000 doses distributed.^{464,465} Several nonfatal pediatric cases have been reported.

Indications

Routine immunization with hepatitis B vaccine is recommended for all infants in the United States and should be completed by 6 to 18 months of age for all infants born to HBsAg-negative mothers.^{34,464} Delivery hospitals should develop policies that ensure administration of a birth dose for all infants weighing 2000 g or more at birth unless a physician's order to defer immunization is in place and the serologic status of the mother is in the infant's medical record. Administering the first dose of hepatitis B vaccine soon after birth should minimize the risk of infection because of errors in maternal HBsAg testing or reporting or from exposure to people with chronic HBV infection in the household and can increase the likelihood of completing the vaccine series. For infants weighing less than 2 kg who are born to HBsAg-negative mothers, initiation of vaccine should begin at 1 month of chronologic age. Administration of the second dose of vaccine is recommended 1 to 2 months after administration of the first dose, followed by a third dose when the infant is 6 to 18 months of age.

Only single-antigen hepatitis B vaccine can be used for doses given to infants between birth and 6 weeks of age. Single-antigen or combination vaccine may be used to complete the series; four doses of vaccine can be administered if a birth dose is given and a combination vaccine containing a hepatitis B component is used to complete the series.

Routine screening of all pregnant women for HBsAg is recommended because of the necessity for administering a birth dose of vaccine and HBIG.^{34,464} Infants born to HBsAg-positive mothers, including preterm and low-birth-weight infants, should be given HBIG (0.5 mL) within 12 hours after birth at a separate injection site, as well as the birth dose of HBV vaccine.^{34,464} If a preterm infant weighing less than 2000 g is born to an HBsAg-positive mother, the birth dose of hepatitis B vaccine should not be counted toward completion of the vaccine series, and three additional doses of hepatitis B vaccine should be administered beginning when the child is 1 month of age. In addition to receiving HBIG and the hepatitis B vaccine series within 12 hours of birth, infants of HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg (i.e., anti-HBs) at 9 to 12 months of age (or 1–2 months after the final dose of the vaccine series, if the series is delayed) to identify those with chronic HBV infection and those who may require revaccination.^{464,582}

A woman whose HBsAg status is unknown at delivery should undergo blood testing as soon as possible to determine it. The infant should receive the first dose of hepatitis B vaccine within 12 hours. If the woman is found to be HBsAg positive, her infant should receive HBIG as soon as possible within 7 days. In populations for which HBsAg testing of pregnant women is not feasible, all infants should receive hepatitis B vaccine at birth and 2 months and complete the series by the time they reach 6 months of age.

Hepatitis B vaccination is recommended for all children and adolescents younger than 19 years in the United States. Children who have not been immunized previously may begin the vaccine series during any visit. All children 11 to 12 years of age should have a review of their immunization records and receive the complete hepatitis B vaccine series if they have not been vaccinated previously. All children and adolescents younger than 19 years who were born in Asia, the Pacific Islands, Africa, or other intermediate- or high-endemic countries or have at least one parent who was born in one of these areas should have a review of their immunization records and complete the hepatitis B vaccine series if they were not vaccinated previously.⁴⁶⁴

TABLE 245.10 Recommended Doses and Schedules of Hepatitis B Virus Vaccines in the United States

Group	VACCINE	
	Recombivax HB Dose μg (mL)	Engerix-B Dose μg (mL)
Infants of HBsAg-negative mothers and children and adolescents <20 y	5 (0.5)	10 (0.5)
Infants of HBsAg-positive mothers (HBIG also recommended)	5 (0.5)	10 (0.5)
Children 1–10 y	5 (0.5) ^a	10 (0.5) ^{a,b}
Adolescents 11–15 y	10 (0.5) ^c	N/A
Adolescents 11–19 y	5 (0.5) ^a	10 (0.5) ^{a,b}
Adults (≥ 20 y)	10 (1.0)	20 (1.0) ^b
Patients undergoing dialysis and other immunocompromised persons		
<20 y ^d	5 (0.5)	10 (0.5)
≥ 20 y	40 (1.0) ^e	40 (2.0) ^f
Unvaccinated adults with diabetes mellitus 19–59 y ^g	10 (1.0)	20 (1.0)

^aPediatric formulation licensed for use in a 3-dose schedule at 0, 12, and 24 months for children 5 to 16 y and at 0, 1, and 6 mo for adolescents 11 to 16 y.

^bAlso licensed as a 4-dose schedule at 0, 1, 2, and 12 mo for all age groups.

^cAdult formulation administered on a 2-dose schedule at 0 mo and then 4 to 6 mo later, licensed for adolescents 11 to 15 y.¹³⁶

^dHigher doses may be more immunogenic, but no specific recommendations have been made.

^eSpecial formulation for patients undergoing dialysis given at 0, 1, and 6 mo.

^fTwo 1.0-mL doses administered as one or two injections in a 4-dose schedule at 0, 1, 2, and 6 mo.

^gThree doses administered at 0, 1, and 6 months.¹⁷²

HBIG, Hepatitis B immune globulin; HBsAg, hepatitis B surface antigen.

Modified from American Academy of Pediatrics. Hepatitis B. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:400–23; Centers for Disease Control and Prevention. A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices (ACIP). Part 1: immunization of Infants, children, and adolescents. *MMWR Recomm Rep*. 2005;54RR-16:1–32.

Vaccination also is recommended for those with one or more of the following risk factors for acquiring HBV infection³⁴:

- Sexually active adolescents and adults who have a recently acquired sexually transmitted disease, are seeking evaluation or treatment for a sexually transmitted infection, are identified as sex workers, or have had one or more sex partners in the previous 6 months
- Sexually active men who have sex with men
- Household contacts or sexual partners of HBsAg-positive people
- Injecting drug users
- People at occupational risk for infection through exposure to blood or blood-contaminated body fluids, such as health care workers and public safety workers
- Residents and staff of institutions for the developmentally disabled
- Patients undergoing hemodialysis (vaccination of those with early renal failure is encouraged before they require hemodialysis)
- Patients with human immunodeficiency virus (HIV) infection, chronic liver disease, or diabetes mellitus
- Members of households with international adoptees who are HBsAg positive
- Travelers, especially children, to areas with high and intermediate rates of infection with HBV who have close contact with the local population or are likely to have contact with blood, such as in a medical setting or by sexual contact with residents
- Inmates in long-term correctional facilities

In addition to active and passive immunoprophylaxis of infants born to HBsAg-positive mothers, postexposure prophylaxis is recommended in the following circumstances:

- Sexual partner of an HBsAg-positive person. A single dose of HBIG within 14 days of the last sexual contact and initiation of the three-dose hepatitis B vaccination is recommended for susceptible people.
- Household exposure or close contact of an unvaccinated infant younger than 12 months old to a primary caregiver who has acute or chronic hepatitis B infection. Infants in this circumstance should receive HBIG and be vaccinated against hepatitis B. If at the time of exposure only one dose of vaccine has been administered, the second dose should be administered if the interval is appropriate, or HBIG should be administered if immunization is not yet due. If the infant has been immunized fully or has received at least two doses of vaccine, the infant should be presumed protected, and HBIG is not required.
- Accidental percutaneous or per mucosal exposure of a susceptible person to HBsAg-positive blood, such as a needlestick or other

accident involving blood in a hospital or an injury to a susceptible person caused by the bite of an HBsAg-positive child. For this indication, HBIG and vaccine are given. Recommendations in these circumstances are complex and based on the availability of the blood source for HBsAg testing and the hepatitis B vaccination status of the exposed person.

Booster doses are not recommended except for patients undergoing hemodialysis and possibly other immunocompromised patients, who should undergo annual antibody testing to assess the need. An additional dose is indicated for those whose serum anti-HBsAg concentration is less than 10 mIU/mL.

The current recommended doses and schedule for the use of hepatitis B vaccines licensed in the United States in infants and other age groups are shown in Table 245.10, and more information can be found elsewhere.^{34,464,465} For completing the hepatitis B vaccine series and achieving complete vaccination for hepatitis B, the two licensed hepatitis B vaccines are interchangeable when administered in doses recommended by the manufacturers.^{34,464} In September 1999, the FDA approved an optional two-dose schedule of Recombivax HB for vaccination of adolescents 11 to 15 years of age. The ACIP recommended that this schedule be included in the VFC program in February 2000.¹³⁶ With the two-dose schedule, the adult dose of Recombivax HB is administered to adolescents 11 to 15 years old, with the second dose given 4 to 6 months after the first dose. In immunogenicity studies enrolling adolescents 11 to 15 years of age, antibody concentrations and seroprotection rates were similar with the two-dose schedule and the currently licensed three-dose schedule. Follow-up data collected during the course of 2 years indicated that the rate of decline in concentration of antibody for the two-dose schedule was similar to that for the three-dose schedule.

No data are available to assess long-term protection or immune memory after vaccination with the two-dose schedule, and whether booster doses of vaccine will be required is not known. Children and adolescents who have begun vaccination with a dose of the pediatric formulation should complete the three-dose series with this dose. Similarly, if the formulation administered to an adolescent at the start of a series is not known, the series should be completed with the three-dose schedule.

A combination of hepatitis B (Engerix-B, 20 μg) and hepatitis A (Havrix, 720 enzyme-linked immunosorbent assay units [ELU]) vaccine (i.e., Twinrix) is licensed for use in people 18 years or older in a three-dose schedule administered at birth, 1 month, and 6 or more months later. An alternative four-dose schedule was approved in 2007; vaccinations

are given at birth, day 7, and between days 21 and 30 and followed by a booster dose at 12 months.³⁴

In December of 2006, the ACIP approved recommendations for hepatitis vaccine use in adults.⁴⁶⁵ In settings in which high proportions of adults are at risk for HBV infection, the ACIP recommends universal hepatitis B vaccination for all unvaccinated adults. Settings include sexually transmitted infection treatment facilities, HIV testing and treatment facilities, facilities providing drug abuse treatment and prevention services, health care settings targeting services to injection drug users, correctional facilities, health care settings serving men who have sex with men, chronic hemodialysis facilities and end-stage renal disease programs, and institutions and nonresidential care facilities for people with developmental disabilities.

For other primary care and specialty medical settings in which adults at risk for HBV infection receive care, the ACIP recommends that health care providers inform all patients about the health benefits of vaccination, including the risk of acquiring HBV infection, and other people for whom vaccination is recommended. They should vaccinate adults who report a risk of developing HBV infection and any adults requesting protection from HBV infection. To promote vaccination in all settings, health care providers should implement standing orders to identify adults recommended for hepatitis B vaccination and administer vaccination as part of routine clinical services, not require acknowledgment of an HBV infection risk factor for adults to receive vaccine, and use available reimbursement mechanisms to remove financial barriers to receiving hepatitis B vaccination.

In 2011, the ACIP recommended that all previously unvaccinated adults 19 through 59 years of age with type 1 or type 2 diabetes mellitus be vaccinated against hepatitis B as soon as possible after a diagnosis of diabetes is made. Unimmunized adults with diabetes mellitus who are 60 years or older may be vaccinated at the discretion of the treating clinician after assessing their risk.¹⁷²

Contraindications

The only contraindication to receiving HBV vaccination is a history of anaphylaxis to a previous dose of vaccine. Data on the safety of HBV vaccines are not available for pregnant women, but because the vaccines contain only HBsAg and not live virus, they should not harm the developing fetus. Because HBV infection during pregnancy can result in transmission to the neonate, susceptible women at increased risk for infection should be vaccinated during pregnancy. Inadvertent vaccination of HBsAg-positive people has no deleterious effects.

Human Papillomavirus Vaccine

Genital HPV infection is thought to be the most common sexually transmitted viral infection, accounting for more than 14 million new cases annually in the United States.⁵⁷⁹ The estimated prevalence of HPV infection among 15- to 19-year-olds is 32.9%, and among 20- to 24-year-old, sexually active women, it is 53.8%.⁵⁷⁹ Prevalence is thought to be similar among males.²⁴⁹ HPV typically infects girls and women soon after sexual exposure.^{208,690} Median time from first intercourse to first detection of HPV is only 3 months.²⁰⁸ The estimated lifetime risk of acquiring HPV infection by those with at least one sexual partner is more than 84% for women and more than 91% for men.¹⁸⁹ More than 80% of women and men acquire HPV infection by 45 years of age.¹⁸⁹

More than 40 HPV types can infect the genital tract and are classified on the basis of their association with cervical cancer.⁴⁹² The low-risk, nononcogenic HPV types (i.e., types 6 and 11) are associated with anogenital warts, mild cervical dysplasia, and recurrent respiratory papillomatosis. The high-risk, oncogenic HPV types are causally linked to several human cancers in women and men, including cancers of the cervix, vulva, vagina, anus, and penis and a subset of head and neck cancers.⁴³⁹ Infection with HPV causes almost all cases of cervical cancer, and before vaccine development, it was the second most common cause of death from cancer among women globally, surpassed only by breast cancer.⁴³⁹ Cervical cancer remains a significant cause of cancer death worldwide.²⁶⁵ The development of cervical cancer often occurs decades after initial infection. HPV types 16 and 18 account for 70% of cervical cancers.¹⁹⁶ A variety of other types account for the remaining 30% of cervical cancers, and these types vary in their distribution globally.

Although the incidence of HPV is high, most infections clear without intervention. Seventy percent of new infections clear within 1 year, and 91% clear within 2 years.¹⁹⁶ Persistent infection with high-risk HPV types, defined as detection of the same viral type at two or more visits 6 months apart, is the most important risk factor for developing cervical cancer precursor lesions. Studies have demonstrated that persistent infection with a high-risk HPV type is associated with a greater than 10-fold risk of high-grade cervical cancer precursors.^{350,483}

Three prophylactic HPV subunit vaccines are licensed and recommended for use in the United States.^{457,533} Use of these vaccines has significantly decreased the prevalence of vaccine-type HPV infection. In one study, vaccine-type HPV prevalence in the study population decreased by 75% among women and more than 90% among vaccinated women.³⁷⁹ Areas with high HPV vaccine coverage have seen decreases in anogenital warts.^{244,245,547} The impact on the incidence of HPV-related cervical and other anogenital cancers will take years to assess because the cancers can occur decades after infection. Incidence of recurrent respiratory papillomatosis and associated cancers also is likely to decrease as a result of widespread vaccination.

Preparations

In 2006, the FDA licensed the first HPV vaccine for use in girls and women 9 through 26 years of age in the United States, and this was done for use in boys and men 9 through 26 years of age in 2009.^{35,167,456} The quadrivalent vaccine (Gardasil, Merck & Co.) contains HPV types 6, 11, 16, and 18 virus-like particles (VLPs) and protects against four HPV types, which together cause 70% of cervical cancers (i.e., HPV types 18 and 16) and 90% of genital warts (i.e., HPV types 6 and 11).

The quadrivalent HPV vaccine (HPV4) is prepared from the highly purified VLPs of the major capsid (L1) protein of HPV types 6, 11, 16, and 18. The L1 proteins are produced by *Saccharomyces cerevisiae* and self-assemble into VLPs. The VLPs mimic the HPV virus, but they contain no viral DNA. Each 0.5-mL dose contains 20 µg of HPV 6 L1 protein, 40 µg of HPV 11 L1 protein, 40 µg of HPV 16 L1 protein, and 20 µg of HPV 18 L1 protein.

A bivalent vaccine (HPV2) (Cervarix, GlaxoSmithKline), which is directed against two oncogenic HPV types (i.e., 16 and 18), was licensed for use in girls and women 10 through 25 years of age in 2009 and not licensed for males.^{35,159}

A 9-valent vaccine (9vHPV) (Gardasil 9, Merck), which protects against the same four HPV types as the quadrivalent HPV vaccine plus HPV 31, 33, 45, 52, and 58 VPs, was approved by the FDA in 2014 and recommended by the ACIP in 2015.^{277,533} It was licensed for use in men and women 9 to 26 years of age.²⁷⁷

The HPV vaccines use alum as an adjuvant and do not contain thimerosal or antibiotics. The vaccines should be stored at 2°C to 8°C (36°F–46°F) and not frozen.¹⁵⁹

Primary vaccination dosing schedules with HPV vaccines are the same and consist of three 0.5-mL doses administered intramuscularly. The second and third doses should be administered 2 and 6 months after administration of the first dose. In 2016, the ACIP recommended that 9- to 14-year-old children receive two HPV vaccine doses instead of the previously recommended three doses because studies showed good immune responses compared with earlier groups receiving three doses.⁴⁷⁴ The recommendation for three doses remained the same for ages 15 to 26 years. The FDA also announced approval of the two-dose schedule for the 9vHPV vaccine.²⁷⁸ Due to licensing and manufacturing issues, 9vHPV will be the primary HPV vaccine going forward.

Immunogenicity and Efficacy

Data from randomized, controlled trials (RCTs) have shown consistently that prophylactic HPV VLP vaccines are immunogenic and efficacious in preventing infection and lesions caused by the targeted HPV types.^{336,402,439,476,616} Vaccine efficacy seems to be mediated by a type-specific humoral immune response.

Evaluations of the quadrivalent HPV4 vaccine have demonstrated that vaccinated individuals develop high antibody titers to the respective HPV types that exceed the antibody titers seen with natural HPV infection.⁶¹⁶ However, the level of antibody that confers a protective response is unknown.⁶¹⁶ For the HPV4 VLP vaccine, an antibody response

significantly greater than placebo was sustained for at least 3 years without booster doses.^{336,663} Although vaccine efficacy studies have been done only enrolling adolescents 13 years or older, immunogenicity bridging studies have been performed with children as young as 9 years of age. Antibody titers to HPV types 6, 11, 16, and 18 were found to be higher in younger adolescents than in young adults. From these data, investigators inferred that protection exists against cervical cancer, cancer precursor lesions, and genital warts, even for young adolescent girls who receive the HPV4 vaccine.

The results from four RCTs demonstrate that a regimen of three intramuscular injections of HPV VLP vaccine provides high-level protection from infection and lesions caused by targeted HPV types.^{402,439} A combined analysis of HPV4 vaccine efficacy in phase II and phase III clinical trials showed 100% protection against precancerous lesions (i.e., carcinoma in situ II/III or adenoma in situ) caused by HPV type 16 or 18 and 99% protection against genital wart development.⁴⁷⁶

A randomized, multicenter, double-blind study found the 9vHPV vaccine antibody response to HPV types 6, 11, 16, and 18 to be non-inferior to the response with the HPV4 vaccine.³⁷⁸ From this result, the 9vHPV vaccine can be inferred to have the same protective efficacy as the HPV4 vaccine. The 9vHPV vaccine prevented infection and disease related to HPV types 31, 33, 45, 52, and 58; for high-grade cervical, vulvar, or vaginal disease related to these HPV types, the vaccine had a 96.7% efficacy rate.³⁷⁸

It is not known whether HPV vaccines provide long-term protection or booster doses will be necessary. The quadrivalent HPV4 vaccine does not have efficacy against existing disease or infection caused by HPV.

HPV2 vaccine efficacy was evaluated in two randomized, double-blind, controlled clinical trials in females 15 through 25 years of age. In the analysis, 99% or more of participants developed an HPV 16 and 18 antibody response 1 month after completing the three-dose series. After concomitant administration of HPV2 with tetanus toxoid, diphtheria toxoid, and acellular pertussis vaccine and/or with meningococcal conjugate vaccine in females 11 through 18 years of age compared with those after administration at separate visits, the antibody responses for bivalent vaccine antigens were noninferior.¹⁵⁹

In summary, HPV vaccines are highly effective in preventing HPV-16 and HPV-18–related cervical precancerous lesions in females. The HPV4 vaccine is highly effective in preventing HPV-6 and HPV-11–related genital warts in females and males, and HPV4 vaccine also is effective in preventing anal precancerous lesions in males. Vaccines offer no protection against progression of infection to disease from HPV acquired before immunization.³⁵

Adverse Events

HPV vaccines appear to be generally safe and well tolerated.⁶²⁰ The HPV4 and 9vHPV vaccines have similar safety profiles.⁵³³ The most common adverse events are local injection site reactions such as mild to moderate pain, redness, pruritus, or swelling.⁵³³ For females 9 to 26 years of age, 9vHPV compared with HPV4 vaccine recipients had more injection site adverse events, including swelling (40.3% vs. 29.1%) and redness (34.0% vs. 25.8%).⁵³³

In analyses of local and general adverse events after bivalent HPV2 vaccine administration versus control vaccines, 92% reported injection site pain, 48%, had redness, and 44% had swelling in the HPV2 group. These findings compared with 64% to 87%, 24% to 28%, and 17% to 21% in the control groups for the same findings. Fatigue, headache, and myalgia were the most common general symptoms reported.¹⁵⁹

Additional data on vaccine safety, including data on pregnancy and fetal and infant outcomes, are being collected. Data will continue to be collected in postlicensure studies.

Indications

The ACIP issued recommendations for the use of the HPV4 vaccine in March 2007, the bivalent HPV2 vaccine in May 2010, and the 9vHPV in March 2015.^{159,160,167,457,456,533} Routine vaccination with three doses of vaccine is recommended for girls 11 to 12 years of age. The vaccination series can be started in girls as young as 9 years of age at the discretion of physicians and parents. Catch-up vaccination is recommended for girls and women 13 to 26 years of age who have not been

vaccinated previously or who have not completed the full vaccination series.

Only HPV4 and 9vHPV vaccines are recommended for routine immunization of boys at 11 or 12 years of age (the series can be started at 9 years of age), and it is recommended for boys and men 13 through 21 years of age not previously immunized.²⁰⁹ Men 22 through 26 years of age may be immunized on request. Vaccine is recommended for men who have sex with men and males who are immunocompromised (including those with HIV infection) through 26 years of age.

Ideally, vaccination should be administered before potential exposure to HPV through sexual contact occurs. HPV vaccines are not licensed for use in people older than 26 years.³⁵

Vaccine is administered in a three-dose schedule, and the second and third doses should be administered 2 and 6 months after the first dose. Immunogenicity data allow for some degree of flexibility in the dosing schedule, which is often an important consideration in providing multidose vaccines to adolescents for whom contact with health providers can be sporadic. For both vaccines, the minimum interval from dose 1 to dose 2 is 4 weeks. The minimum interval from dose 2 to dose 3 should not be less than 12 weeks. For ages 9 to 14 years, vaccine can be administered in a two-dose schedule, with the second dose administered at least 6 months after the first dose. The three-dose schedule should be used for ages 15 to 26 years.⁴⁷⁴

HPV vaccine can be administered at the same visit when other age-appropriate vaccines, such as Tdap, Td, and MCV4 (meningococcal), are provided.⁵⁰⁸ Women who have received an HPV vaccine must continue to have regular Papanicolaou test screening. HPV vaccines do not provide protection against all HPV types associated with development of cancer, and vaccines do not alter the progression of HPV infection acquired before immunization.

People through 26 years of age with evidence of current HPV infection, such as cervical dysplasia, a positive HPV DNA test result, or anogenital warts or a history of anogenital warts, should receive HPV immunization because infection with all vaccine HPV types is unlikely and the vaccine can provide protection against HPV infection with types not already acquired.³⁵ Vaccine recipients should be advised that data from clinical trials do not indicate the vaccine will have any therapeutic effect on existing abnormalities found by Papanicolaou testing, on HPV infection, or on genital warts. However, HPV vaccination can provide protection against infection with HPV types not already acquired.

Lactating women can receive HPV4 or 9vHPV vaccine, but the bivalent vaccine has not been studied in lactating women. Patients of the appropriate age who are immunocompromised due to disease or medication can receive HPV vaccine. However, the immune response to vaccination and vaccine effectiveness may be less than in those who are immunocompetent.

Contraindications and Precautions

HPV4 and 9vHPV vaccines are contraindicated for people with a history of immediate hypersensitivity to yeast or to any vaccine component.⁵³³ Bivalent HPV2 vaccine is contraindicated for people with a history of immediate hypersensitivity to any vaccine component. HPV2 vaccine in the prefilled syringe formulation should not be administered to latex-sensitive individuals because the rubber stopper contains latex.³⁵

HPV vaccine is listed under pregnancy category B and is not recommended for use in pregnancy.^{159,457} If an adolescent becomes pregnant during the vaccination period, subsequent doses should be deferred until after parturition. The vaccine has not been associated causally with adverse outcomes of pregnancy or adverse effects on the developing fetus. However, data on vaccination during pregnancy are limited.

Influenza Vaccine

Influenza virus infection continues to cause significant morbidity and mortality despite the availability of effective vaccines and antiviral therapy for prevention and treatment of influenza. In the United States, epidemics of influenza typically occur during the winter months and have been associated with an average of approximately 36,000 deaths per year, and between 1976 and 2007, estimated cases ranged from 3000 to 49,000 each year.^{158,638}

Influenza viruses cause disease among all age groups.^{300,301,486} Rates of infection are highest among children, but rates of serious illness and death are highest among those 65 years or older, children 2 years or younger, and people of any age who have medical conditions that increase the risk of complications from influenza.^{65,64,299,486} The impact of influenza on normal children and those with underlying high-risk conditions is appreciable, and the burden of disease in young children attributed to influenza is underrecognized.⁵⁴² Attack rates among normal children have been estimated at 10% to 40% each year, and approximately 1% of influenza infections result in hospitalization.^{302,542} Influenza also causes a significant burden in outpatient settings, especially for those 2 to 17 years of age.²⁷⁹

A major difficulty in the development and provision of satisfactory immunizing agents for the prevention of influenza is the antigenic variation of the viruses. Periodic minor antigenic changes in influenza A or B virus are the major factors in the continuing occurrence of yearly influenza. Although outbreaks usually are limited in magnitude, the resulting morbidity and mortality remain discouragingly high. Major antigenic changes in influenza A virus, as occurred in 1957 to 1958 (Asian strain), in 1968 to 1969 (Hong Kong strain), and again in 2009 (pH1N1) account for the pandemic spread of disease associated with greater overall morbidity and mortality. The CDC estimates that in the 2009 pandemic the H1N1 influenza virus caused more than 60 million Americans to become ill and led to more than 270,000 hospitalizations and 12,500 deaths.³⁷¹ People younger than 65 years accounted for 90% of hospitalizations and deaths. With typical seasonal influenza, approximately 90% of the people who die are older than 65 years.

Preparations

An assortment of influenza vaccines are licensed for use in the United States: inactivated trivalent influenza vaccine (IIV3), adjuvanted inactivated trivalent influenza vaccine (aIIV3), recombinant trivalent influenza vaccine (RIV3), inactivated quadrivalent influenza vaccine (IIV4), inactivated quadrivalent cell culture-based influenza vaccine (ccIIV4), and live attenuated quadrivalent influenza vaccine (LAIV).^{101,315}

The trivalent vaccines contain three virus strains (usually two type A and one type B), and the composition is changed periodically in anticipation of the prevalent influenza strains expected to circulate in the United States in the following winter. The quadrivalent vaccines include an additional type B strain.³¹⁵ Most vaccines are prepared from virus grown in the allantoic sac of the chick embryo. Exceptions include one IIV4 preparation with virus propagated through canine kidney cells and the RIV3 preparation, which is manufactured without the use of influenza viruses.³¹⁵

IIV3, aIIV3, IIV4, and ccIIV4 are inactivated influenza vaccines (IIVs) that contain no live virus. IIVs distributed in the United States consist of subvirion vaccine, prepared by disrupting the lipid-containing membrane of the virus, or purified surface-antigen vaccine. All IIV formulations are available for intramuscular use, except ccIIV4, which is intradermal.

IIV4 is licensed and recommended for children 6 months or older and for adults, including those with or without chronic medical conditions. Vaccine is available in pediatric (0.25-mL dose) and adult (0.5-mL dose) formulations. IIV3 and ccIIV4 (using the 0.5-mL dose) are licensed and recommended for children 4 years or older and for adults. RIV3, also in the 0.5-mL dose, is licensed and recommended for those 18 years or older.

IIV is administered intramuscularly into the anterolateral thigh of infants and young children and into the deltoid muscle of older children and adults. RIV3 is administered intramuscularly into the deltoid muscle. The volume of vaccine depends on age. Infants and toddlers 6 months through 35 months of age should receive a dose of 0.25 mL, and all individuals 36 months or older should receive 0.5 mL per dose. Children younger than 9 years who are being immunized against influenza for the first time should receive two doses of TIV given 4 weeks apart before the start of the influenza season. IIV is shipped and stored at 2°C to 8°C (35°F–46°F).

The intradermal formulation of IIV4 is licensed for the 2016–2017 influenza season for use in individuals 18 through 64 years of age.³¹⁵ It is administered preferably over the deltoid muscle and only by using

the device included in the vaccine package. Vaccine is supplied in a single-dose, prefilled microinjection system (0.1 mL). The intradermal formulation of IIV4 is shipped and stored at 2°C to 8°C (35°F–46°F).

Many manufacturers produce inactivated influenza vaccine each year for the US market. Vaccines are available in single-dose syringes and vials or multidose vials and in preservative-free formulations. Approved age indications vary by manufacturer and product. Clinicians should obtain inactivated influenza vaccine appropriate for the age groups they plan to vaccinate. The ACIP does not recommend use of influenza vaccine outside the vaccine's FDA-approved age indication. Tables listing each year's influenza vaccines are available in the annual ACIP and AAP influenza statements and on the CDC influenza website (https://www.cdc.gov/flu/professionals/vaccination/vaccine_safety.htm). Package inserts should be consulted for recommended age groups and possible contraindications for each vaccine in addition to information regarding additional components of various vaccine formulations.

LAIV is cold adapted, developed by passaging the viruses at successively lower temperatures in tissue culture so that replication occurs only in the upper respiratory tract.⁷⁴ LAIV is licensed by the FDA for healthy individuals 2 through 49 years of age. It has not been recommended for those with a history of asthma or other high-risk medical conditions associated with an increased risk of complications from influenza.

LAIV is administered intranasally in a prefilled, single-use sprayer containing 0.2 mL of vaccine. A removable dose-divider clip is attached to the sprayer to administer 0.1 mL separately into each nostril. Children younger than 9 years being immunized against influenza for the first time should receive two doses of LAIV given 4 weeks apart before the start of the influenza season. The LAIV formulation licensed in the United States must be shipped and stored at 2°C to 8°C (35°F–46°F). After the vaccine is warmed to room temperature for intended use, it must be used within 30 minutes.

Trivalent influenza vaccines contain A (H1N1), A (H3N2), and B viral antigens. The quadrivalent influenza vaccines include an additional B viral antigen because of the difficulty of predicting which B virus lineage will predominate during a given season.

Immunogenicity and Efficacy

Children 6 months or older typically have protective levels of anti-influenza antibody against specific influenza virus strains after receiving the recommended number of doses of seasonal inactivated influenza vaccine.^{226,305,417,499,702,704} Immunogenicity studies using the influenza A (H1N1) 2009 monovalent vaccine indicated that more than 90% of children 9 years or older responded to a single dose with anti-influenza antibody levels considered to be protective. Young children had inconsistent responses to a single dose of the influenza A (H1N1) 2009 monovalent vaccine across studies, with 20% of children 6 to 35 months of age responding to a single dose with protective anti-influenza antibody levels. However, in all studies, 80% to 95% of vaccinated infants, children, and adolescents developed protective anti-influenza antibody levels to the 2009 H1N1 influenza virus after two doses.^{56,506,538}

In most seasons, one or more seasonal vaccine antigens are changed compared with the previous season. In consecutive years when vaccine antigens change, children younger than 9 years who received only one dose of vaccine in their first year of vaccination are less likely to have protective antibody responses when administered only a single dose during their second year of vaccination compared with children who received two doses in their first year of vaccination.^{258,502,668}

When the vaccine antigens do not change from one season to the next, priming children 6 to 23 months of age with a single dose of vaccine in the spring followed by a dose in the fall results in similar antibody responses compared with a regimen of two doses in the fall.²⁵⁷ However, one study conducted during a season when the vaccine antigens did not change compared with the previous season estimated 62% effectiveness against influenza-like illness for healthy children who had received only one dose in the previous influenza season and only one dose in the study season compared with 82% for those who received two doses separated by 4 weeks or more during the study season.¹⁰

The antibody response for children at higher risk for influenza-related complications (e.g., children with chronic medical conditions) may be

lower than those reported typically for healthy children.^{71,316} However, antibody responses among children with asthma are similar to those of healthy children and are not substantially altered during asthma exacerbations requiring short-term prednisone treatment.⁵²²

Vaccine effectiveness studies also have indicated that two doses are needed to provide adequate protection during the first season that young children are vaccinated. Among children younger than 5 years who have never received influenza vaccine previously or who received only one dose of influenza vaccine in their first year of vaccination, vaccine effectiveness is lower compared with children who received two doses in their first year of being vaccinated. Two large, retrospective studies of young children who had received only one dose of IIV in their first year of being vaccinated found no decrease in influenza-like illness–related office visits compared with unvaccinated children.^{10,558} Similar results were reported in a case-control study of children 6 to 59 months of age in which laboratory-confirmed influenza was the outcome measured.⁶⁰² These results, along with the immunogenicity data indicating that antibody responses are substantially higher when young children are given two doses, are the basis for the recommendation that all children 6 months to 8 years of age who are being vaccinated for the first time should receive two vaccine doses separated by 4 weeks or more.

Estimates of vaccine efficacy or effectiveness among children 6 months or older have varied by season and study design. In a randomized trial conducted during five influenza seasons (1985–90) in the United States for children 1 to 15 years of age, annual vaccination reduced laboratory-confirmed influenza A substantially (77–91%).⁵⁰¹ A 1-year, placebo-controlled study reported vaccine efficacy rates against laboratory-confirmed influenza illness of 56% for healthy children 3 to 9 years of age and 100% for healthy children and adolescents 10 to 18 years old.¹⁹⁷

A randomized, double-blind, placebo-controlled trial conducted during two influenza seasons among children 6 to 24 months of age indicated that the efficacy rate was 66% against culture-confirmed influenza illness during the 1999–2000 influenza season but did not reduce culture-confirmed influenza illness substantially during the 2000–01 influenza season.³⁵¹ A case-control study conducted during the 2003–04 season indicated vaccine effectiveness of 49% against laboratory-confirmed influenza.⁶⁰² An observational study of children 6 to 59 months of age with laboratory-confirmed influenza compared with children who tested negative for influenza reported vaccine effectiveness of 44% in the 2003–04 influenza season and 57% during the 2004–05 season.²⁵⁵ Partial vaccination (i.e., only one dose for children being vaccinated for the first time) was not effective in either study.

During an influenza season (2003–04) with a suboptimal vaccine match, a retrospective cohort study conducted among approximately 30,000 children 6 months to 8 years of age indicated vaccine effectiveness of 51% against medically attended, clinically diagnosed pneumonia or influenza (i.e., no laboratory confirmation of influenza) among fully vaccinated children and 49% among approximately 5000 children 6 to 23 months old.⁵⁵⁸

Another retrospective cohort study of similar size conducted during the same influenza season in Denver but limited to healthy children 6 to 21 months of age estimated clinical effectiveness of 2 IIV doses to be 87% against pneumonia or influenza-related office visits.¹⁰

Among children, TIV effectiveness may increase with age.^{501,711} A systematic review of published studies estimated vaccine effectiveness at 59% for children 2 years or older but concluded that additional evidence was needed to demonstrate effectiveness among children 6 months to 2 years old.³⁷⁰

Because of the recognized influenza-related disease burden among children with other chronic diseases or immunosuppression and the long-standing recommendation for vaccination of these children, randomized, placebo-controlled studies to determine efficacy in high-risk children are needed but are currently unavailable. Although data about influenza vaccine in specific immunocompromised states are limited, the Infectious Diseases Society of America (IDSA) publishes guidelines for specific immune-compromising diagnoses.⁵⁶⁸ In a nonrandomized, controlled trial enrolling children 2 to 6 years old and 7 to 14 years old who had asthma, vaccine efficacy was 54% and 78% against laboratory-confirmed influenza type A infection and 22% and 60% against

laboratory-confirmed influenza type B infection, respectively. Vaccinated children 2 to 6 years of age with asthma did not have substantially fewer type B influenza virus infections compared with the control group in this study.⁶²³

The association between vaccination and prevention of asthma exacerbations is unclear. Vaccination provided protection against asthma exacerbations in some studies.^{403,511}

IIV has reduced AOM in some studies. Two studies reported that IIV decreased the risk of influenza-related otitis media by approximately 30% among children with mean ages of 20 and 27 months, respectively.^{194,339} However, a large study conducted among children with a mean age of 14 months indicated that IIV was not effective against AOM.³⁵¹ Influenza vaccine effectiveness against a nonspecific clinical outcome such as AOM, which is caused by a variety of pathogens and is not typically diagnosed using influenza virus culture, is expected to be relatively low.

The relative effectiveness of LAIV and IIV for medically attended, laboratory-confirmed influenza was evaluated using US Influenza Vaccine Effectiveness Network data.¹⁹² For the 2013–14 season, children 2 to 8 years of age who received LAIV had significantly higher odds of influenza (odds ratio, 5.36) than those who received IIV.¹⁹² The greater odds of illness with influenza A/H1N1pdm09 included the 2010–11 and 2013–14 seasons. Another study of the 2013–14 season found the effectiveness of LAIV against influenza A/(H1N1)pdm09 to be 17%, compared with 60% for IIV, for children 2 to 17 years of age.²⁸⁴

After the ACIP recommendation for preferential use of LAIV during the 2014–15 season for children 2 to 8 years of age, another study examined vaccine effectiveness by type.⁷¹⁶ In this study with 9311 participants at 5 US sites, the preference for use of LAIV in young children was not supported. Based on these and several other studies, LAIV was not recommended for use for any age for the 2016–17 season.^{101,315}

Adverse Events

All inactivated influenza vaccines contain killed viruses and therefore cannot produce signs or symptoms of influenza caused by active virus infection. The most common symptoms associated with IIV administration are soreness at the injection site and fever. Fever, usually occurring 6 to 24 hours after immunization, affects 10% to 35% of children younger than 2 years. Mild systemic symptoms, such as nausea, lethargy, headache, muscle aches, and chills also can occur after receipt of IIV.

Before the 2010–11 influenza season, an increased risk of febrile seizures after IIV3 administration had not been observed in the United States.^{313,329} The CDC and the FDA conducted enhanced monitoring for febrile seizures after influenza vaccination because of reports of an increased risk of fever and febrile seizures in young children in Australia that were associated with a 2010 Southern Hemisphere vaccine produced by CSL Biotherapies. The risk was up to nine febrile seizures per 1000 doses during the 2010–11 influenza season. Due to the increased risk, the ACIP does not recommend the US licensed Afluria (CSL Biotherapies' IIV3) for children younger than 9 years.¹⁶⁴

For the 2010–11 season, surveillance for US licensed influenza vaccines detected safety signals for febrile seizures in younger children after IIV administration.^{426,645} On further review, the increased risk was found for children 6 months through 4 years of age, ranging from the day of vaccination to the day after vaccination (i.e., 0–1-day risk window). The risk was found to be higher when children received concomitant PCV13, and the risk peaked at about 16 months of age.⁶⁴⁵ No increased risk was observed for children 5 years or older after IIV or for children of any age after LAIV. The magnitude of the increased risk of febrile seizures in young children in the United States (<1 case/1000 children vaccinated) was substantially lower than the risk observed in Australia in 2010.

After evaluating the data on febrile seizures from the 2010–11 influenza season and taking into consideration benefits and risks of vaccination, no policy change was recommended for use of IIV or PCV13. According to the CDC, surveillance data on febrile seizures in young children after administration of influenza vaccine for the 2011–12 influenza season (i.e., same vaccine formulation as for the 2010–11 season) were consistent with those from the 2010–11 influenza season. No changes in the use of IIV or PCV13 are recommended, although surveillance is ongoing.³¹⁵

LAIV usually is well tolerated and may produce mild signs or symptoms related to influenza virus infection that include headache and runny nose or nasal congestion in vaccinees. Transmission of LAIV strains to unimmunized contacts has been documented only once in precensure studies. The proposed explanation for the uncommon occurrence of transmission is that the vaccine virus is shed for a shorter duration and in a much smaller quantity than are wild-type strains.

Indications

Routine annual influenza vaccination is recommended for all people 6 months or older.^{37,101,315} To permit time for production of protective antibody levels,^{91,317} vaccination optimally should occur before the onset of influenza activity in the community. Vaccination providers should offer vaccination as soon as the vaccine is available. Vaccination should be offered throughout the influenza season (i.e., as long as influenza viruses are circulating in the community).^{101,315} Due to the previously described issues with vaccine effectiveness, LAIV was not recommended by the ACIP for any age group for the 2016–17 influenza season.³¹⁵

Particular focus should be on the administration of IIV for all children and adolescents who have underlying medical conditions associated with an increased risk of complications from influenza, including the following:

- Asthma or other chronic pulmonary diseases, including cystic fibrosis
- Hemodynamically significant cardiac disease
- Immunosuppressive disorders or therapy
- HIV infection
- Sickle cell anemia and other hemoglobinopathies
- Diseases that require long-term aspirin therapy, including juvenile idiopathic arthritis or Kawasaki disease
- Chronic renal dysfunction
- Chronic metabolic disease, including diabetes mellitus
- Any condition that can compromise respiratory function or handling of secretions or can increase the risk of aspiration, such as neurodevelopmental disorders, spinal cord injuries, seizure disorders, or neuromuscular abnormalities

Although universal immunization for all individuals 6 months or older is recommended, particular immunization efforts should be made for the following groups to prevent transmission of influenza to those at risk, unless contraindicated:

- Household contacts and out-of-home care providers of children younger than 5 years and at-risk children of all ages should be immunized.
- Any female who is pregnant, is considering pregnancy, has just delivered, or is breastfeeding during the influenza season should be immunized. Studies have shown that infants born to immunized women have better influenza-related health outcomes. However, the estimated median seasonal vaccination coverage among women with a live birth was only 47% during the 2009–10 influenza season, even though pregnant women and their infants are at higher risk for complications. Data from some studies suggest that influenza vaccination during pregnancy may decrease the risk of preterm birth.
- Health care personnel or health care volunteers should be immunized. Despite the recent AAP recommendation for mandatory influenza immunization for all health care personnel,^{76,101} many remain unvaccinated. The CDC estimated that only 77% of health care personnel received the seasonal influenza vaccine for the 2014–15 season.⁸¹ The AAP recommends mandatory vaccination of health care personnel because they frequently come into contact in their clinical settings with patients at high risk for influenza illness.
- Close contacts of immunosuppressed individuals should be immunized.

Previously unimmunized children between 6 months to 9 years of age should receive two doses of influenza vaccine before the onset of influenza season. Available data suggest that children younger than 9 years who did not receive the second dose of influenza vaccine in the initial year that influenza vaccine was given may not be adequately protected the next influenza season with only one dose. In this group, levels of protection can be suboptimal, especially if the antigenic specificity of the predominant strains has changed from the previous

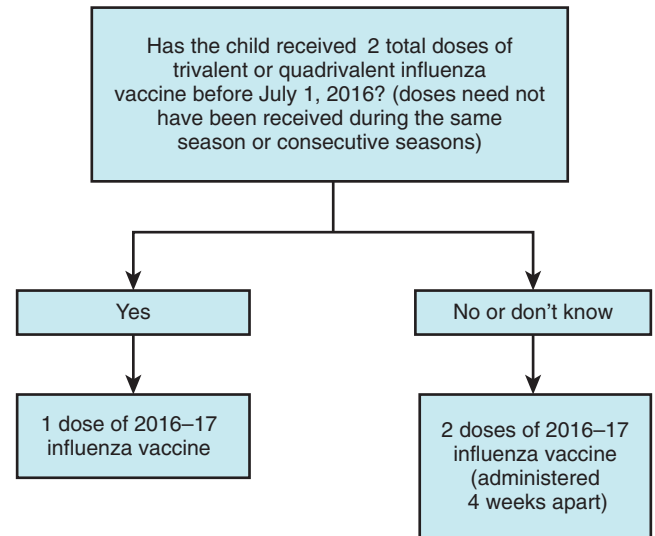

FIG. 245.2 Influenza vaccine dosing algorithm for children age 6 months through 8 years for the US 2016–17 influenza season. (From Centers for Disease Control and Prevention. Prevention and control of seasonal influenza with vaccines recommendations of the Advisory Committee on Immunization Practices—United States, 2016–17 influenza season. <https://www.cdc.gov/mmwr/volumes/65/rr/rr6505a1.htm>.)

year. The AAP recommends that two doses be given to these children the following influenza season.¹⁰¹ This recommendation applies only to the influenza season that follows the first year that a child younger than 9 years old receives influenza vaccine (Fig. 245.2).

Precautions and Contraindications

IIVs are contraindicated for infants younger than 6 months and children who have a moderate to severe febrile illness on the basis of clinical judgment of the pediatrician.¹⁷⁹ People with acute febrile illness usually should not be vaccinated until their symptoms have abated. However, minor illnesses with or without fever do not contraindicate the use of influenza vaccine, particularly in children with mild upper respiratory tract infection or allergic rhinitis.^{101,315}

Pregnancy is not a contraindication to influenza vaccine administration. Vaccination with IIVs are advised for pregnant girls and women who have an underlying high-risk condition.

IIVs can be used to prevent influenza in those who are in close contact with most immunosuppressed individuals, such as those receiving care in a protective environment after undergoing hematopoietic stem cell transplantation.

Severe allergic and anaphylactic reactions can occur in response to several influenza vaccine components, but such reactions are rare. Currently available influenza vaccines are prepared by means of inoculation of virus into chicken eggs, with the exception of the RIV3 and ccIIV4 preparations.³¹⁵ The use of influenza vaccines for people with a history of egg allergy was reviewed by the ACIP.³¹⁵ For the 2016–17 influenza season, the ACIP recommended that people with egg allergy who report only hives after egg exposure should receive IIVs, with several additional safety measures. For the 2016–17 influenza season, the ACIP recommended the following:

- People with a history of egg allergy who have experienced only hives after exposure to egg should receive influenza vaccine.³¹⁵
- People who report having had reactions to egg involving symptoms such as angioedema, respiratory distress, lightheadedness, or recurrent emesis or who required epinephrine or another emergency medical intervention, particularly those that occurred immediately or within minutes to hours after egg exposure, should receive influenza vaccine.³¹⁵

Measles Vaccine

Since the introduction of an inactivated and a live virus, attenuated measles vaccine (i.e., Edmonston B strain) in the United States in 1963,

the reported incidence of measles has decreased by more than 99%. Although the incidence of measles has declined in all age groups, the decline has been greatest among children 5 to 14 years of age.

Measles was targeted for elimination in the United States by 1982. Efforts to eliminate measles were not successful as a result of two factors. The first was vaccine failure. In the late 1980s, outbreaks occurred among older children in schools in which immunization rates usually were greater than 95%.^{459,505} Attack rates were 1% to 5% because of the accumulation of measles-susceptible individuals from vaccine failure. The recurrent measles outbreaks among vaccinated school-aged children in the mid-1980s prompted the ACIP and the AAP in 1989 to recommend that all children be given two doses of measles-containing vaccine, preferably as MMR.^{13,109} Although administration of the second dose originally was recommended at entry to primary school (ACIP) or middle/secondary school (AAP), the ACIP, the AAP, and the AAPF now recommend that a child be given the second dose at age 4 to 6 years rather than delaying it until the child is 11 to 12 years old.^{38,471} The major benefit of administering the second dose is a reduction in the proportion of people who remain susceptible because of primary vaccine failure. Waning immunity is not a major cause of vaccine failure and has little influence on transmission of measles, and revaccination of children who have low concentrations of measles antibody produces only a transient rise in antibody concentration.^{454,458,505,518,669}

The second factor leading to outbreaks of measles was the failure to implement current immunization strategies, especially in the inner cities, where a high proportion of preschool-aged children had not been vaccinated. From 1989 through 1991, the proportion of unvaccinated people with measles increased, as reflected by outbreaks among unvaccinated inner-city preschool-aged children. Many barriers to providing timely immunization to these children were identified during investigation of the measles resurgence that occurred between 1989 and 1991. Reported cases of measles declined rapidly after the 1989–91 resurgence because of intensive efforts to vaccinate preschool-aged children. Measles vaccination levels among 2-year-old children increased from 70% in 1990 to 91% in 1997. From 2001 to 2008, a median of 56 measles cases were reported to the CDC annually.⁵²³

In 2000, the United States achieved measles elimination, defined as interruption of year-round endemic measles transmission.³⁸² However, importations of measles into the United States continue to occur, posing risks for measles outbreaks and sustained measles transmission. Since 2000, the annual number of cases has ranged from a low of 37 in 2004 to a high of 667 in 2014.^{267,287} Most cases have been among people who are not vaccinated against measles. Most cases are imported from other countries or linked to imported cases. Most imported cases originate in Asia, Africa, and Europe and occur among US citizens traveling abroad and people visiting the United States from other countries.⁶¹⁴ Since 1993, the largest outbreaks of measles in the United States have occurred in populations that refuse vaccination for religious or personal belief reasons.^{534,610} Most outbreaks have involved limited spread from measles imported from outside the United States. The increased numbers of outbreaks and measles importations into the United States underscore the ongoing risk of measles among unvaccinated people and the importance of vaccination against measles.

The recommended age for receiving routine vaccination with measles vaccine has been lowered in the past decade from 15 months to 12 to 15 months of age.¹⁴¹ The decision to lower the age for receiving routine primary vaccination was based on the observation that most children are susceptible to measles by the time that they reach 12 months of age because of waning transplacental immunity.^{447,455} Most mothers have vaccine-induced immunity rather than immunity conferred by infection with wild virus. Because antibody concentrations induced by measles vaccination typically are lower than those induced by natural measles, measles-specific antibodies acquired transplacentally are lower in infants of vaccinated mothers, and these infants are susceptible at an earlier age.

Preparations

The live measles virus vaccine (Moraten strain) available in the United States is prepared in chick fibroblast cell culture. Each dose of vaccine contains neomycin, sorbitol, and hydrolyzed gelatin as a stabilizer. Preparations include MMR and measles-mumps-rubella-varicella

(MMRV) vaccines. MMRV vaccine was licensed in the United States in September 2005 and may be used instead of MMR and varicella vaccine to implement the recommended two-dose vaccine schedule for prevention of measles, mumps, rubella, and varicella among children 12 months to 12 years of age. Single-component measles vaccine is not available in the United States.

Inadequate protection against measles can result from the administration of improperly stored vaccine. Before reconstitution, measles vaccine must be stored at a temperature between 2°C and 8°C (35.6°F–46.4°F) or colder and must be protected from light, which may inactivate the virus. Reconstituted vaccine should be stored in a refrigerator and discarded if not used within 8 hours.

Immunogenicity and Efficacy

Immunization produces a mild or unapparent, noncommunicable infection. Measles antibodies develop in approximately 95% of children vaccinated at 12 months of age and in 98% of children vaccinated at 15 months of age.⁴⁵⁵ Studies indicate that serologic evidence of measles immunity develops in more than 99% of people who receive two doses of measles vaccine, separated by at least 1 month, on or after their first birthday.^{191,206} Although vaccine-induced antibody titers are lower than those after natural disease, persistence of protective titers for as long as 16 years after administration of vaccine has been demonstrated.^{410,458} Most vaccinated people who appear to lose antibody have an anamnestic response after revaccination, indicating that they most likely are still immune.⁵¹⁴ A small percentage of vaccinated individuals may lose protection after several years as a result of secondary vaccine failure.⁴⁶⁶

Adverse Events

Vaccine-associated symptoms, consisting of fever higher than 39.4°C (102.9°F) or rash occurring 5 to 10 days after immunization, develop in 5% to 18% of recipients.^{421,530} Serious complications related to vaccine use occur far less frequently than after natural measles.⁵²⁵

Thrombocytopenia occurs at a rate of one case for every 30,000 to 40,000 doses distributed. Based on data from Sweden and Finland, the IOM concluded that a causal association exists between MMR and thrombocytopenia.³⁶² The decrease in platelet count presumably is caused by the measles component and usually is not clinically apparent. However, thrombocytopenic purpura occurring after vaccination has been reported.

Central nervous system disease, specifically encephalitis or encephalopathy, is reported at a rate of less than one case per 1 million doses of vaccine administered. Because the incidence of encephalitis or encephalopathy after the administration of measles vaccination to healthy children is lower than the observed incidence of encephalitis of unknown origin, some or most of the reported severe neurologic disorders may be only temporally, rather than causally, related to measles immunization. The risk of subacute sclerosing panencephalitis (SSPE) developing in vaccinated children is extremely low and is estimated to be approximately one twelfth of the risk for SSPE developing after a case of natural measles (0.7 SSPE cases/1 million vaccine doses vs. 8.5 cases/1 million natural measles infections).^{82,106,362} Vaccine-strain measles virus never has been confirmed in a case of SSPE.³⁸

Reactions to measles vaccine are not age related and occur only in susceptible vaccinees. After revaccination, reactions should be expected only in those who failed to respond to the first immunization.

No convincing evidence establishes that any vaccine causes autism or autistic spectrum disorder. Concern has been raised about a possible relation between MMR vaccine and autism by some parents of children with autism. Symptoms of autism often are noticed by parents during the second year of life and may manifest after administration of MMR by weeks or months. Two independent nongovernmental groups, the IOM and the AAP, reviewed the evidence regarding a potential link between autism and MMR vaccine.^{328,360,361} Both groups independently concluded that available evidence does not support an association and that the United States should continue its current MMR vaccination policy.

Indications

Unless otherwise contraindicated, measles vaccine is indicated for people susceptible to measles.^{38,471} The recommended age for receiving the first

dose of measles vaccine is 12 to 15 months. In high-risk areas, such as those with recurrent measles transmission, the initial dose should be administered when the child reaches 12 months of age. The second dose is given routinely at 4 to 6 years and no later than 11 to 12 years of age. The minimal interval between the two doses is 4 weeks.

Adults born before 1957 usually can be considered immune to measles because of previous natural infection. Those born after 1956 and for whom immunoprophylaxis is indicated should receive two doses of vaccine.

During outbreaks, when the likelihood of exposure to measles is high, measles vaccine should be given to infants as young as 6 months. Seroconversion rates are significantly less for children vaccinated before reaching 1 year of age than those for older children. Children immunized before their first birthday then should be revaccinated with MMR at 12 to 15 months of age, with a third dose given according to local policy.

Measles remains endemic in many areas of the world. Although vaccination against measles is not a requirement for entry into any country, susceptible children, adolescents, and adults born after 1956 should be offered measles vaccination (usually as MMR) before embarking on international travel. Infants 6 months or older who are traveling to areas where measles is endemic or epidemic should be vaccinated before departure and revaccinated at 12 to 15 months. Vaccination of infants younger than 6 months is not necessary because most young infants are protected by maternally derived antibodies.

Exposure of susceptible individuals to measles is not a contraindication to administering vaccination; MMR vaccine given within 72 hours of exposure may provide protection. For vaccine-eligible people 12 months or older who are exposed to measles, administration of MMR vaccine is preferable to using immune globulin if administered within 72 hours of initial exposure. If exposure does not result in infection, immunization will protect against future infection.

MMRV vaccine may be used instead of MMR and varicella vaccine to implement the recommended two-dose vaccine schedule for children 12 months to 12 years of age. At the time of its licensure, use of MMRV vaccine was preferred for the first and second doses over separate injections of equivalent component vaccines (i.e., MMR vaccine and varicella vaccine), which was consistent with the ACIP's 2006 general recommendations on the use of combination vaccines.⁴⁰⁷

In February 2008, on the basis of preliminary data from two studies conducted after licensure that suggested an increased risk of febrile seizures 5 to 12 days after vaccination among children 12 to 23 months of age who had received the first dose of MMRV vaccine compared with children the same age who had received the first dose of MMR vaccine and varicella vaccine administered as separate injections at the same visit, the ACIP issued updated recommendations regarding MMRV vaccine use.¹⁵⁵ The updated recommendations expressed no preference for use of MMRV vaccine over separate injections of equivalent component vaccines for the first and second doses.

The final results of the two postlicensure studies indicated that among children 12 to 23 months of age, one additional febrile seizure occurred 5 to 12 days after vaccination per 2300 to 2600 children who had received the first dose of MMRV vaccine compared with children who had received the first dose of MMR vaccine and varicella vaccine administered as separate injections at the same visit.³⁹⁴ Data from postlicensure studies do not suggest that children 4 to 6 years of age who received the second dose of MMRV vaccine had an increased risk of febrile seizures after vaccination compared with children the same age who received MMR vaccine and varicella vaccine administered as separate injections at the same visit.³⁹⁵

In June 2009, after consideration of the postlicensure data and other evidence, the ACIP adopted new recommendations regarding use of MMRV vaccine for the first and second doses and identified a personal or family (i.e., sibling or parent) history of seizure as a precaution for the use of MMRV vaccine.⁴⁵⁰ For the first dose of measles, mumps, rubella, and varicella vaccines at 12 to 47 months of age, the MMR vaccine and varicella vaccine or MMRV vaccine may be used. Providers who are considering administering MMRV vaccine should discuss the benefits and risks of vaccination options with the parents or caregivers. Unless the parent or caregiver expresses a preference for MMRV vaccine, the CDC recommends that MMR vaccine and varicella vaccine should

be administered for the first dose in this age group. For the second dose of measles, mumps, rubella, and varicella vaccines at any age (i.e., 15 months to 12 years) and for the first dose at an age older than 48 months, use of MMRV vaccine usually is preferred over separate injections of its equivalent component vaccines (i.e., MMR vaccine and varicella vaccine). This recommendation is consistent with the ACIP's 2011 general recommendations regarding use of combination vaccines, which state that use of a combination vaccine usually is preferred over its equivalent component vaccines.⁴⁰⁸

Precautions and Contraindications

Immunocompromised patients with conditions such as lymphoreticular or other generalized malignant disease and primary or secondary immunodeficiency states should not be given live virus, attenuated measles vaccine.^{38,471} After cessation of their chemotherapy, these individuals usually should not receive measles vaccine for at least 3 months. However, because the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors determine when immunologic responsiveness will be restored, arriving at a definitive recommendation for an interval after cessation of immunosuppressive therapy when measles vaccine can be safely and effectively administered often is not possible.

An exception to the contraindication of administering measles vaccine to immunocompromised patients is asymptomatic HIV-infected patients, for whom measles vaccination given as MMR at 12 to 15 months of age is recommended. The need to protect HIV-infected people who are at increased risk for severe complications if infected with measles has been balanced against the risk of adverse reactions. Measles vaccine is not recommended for HIV-infected people with evidence of severe immunosuppression. A case of progressive measles pneumonitis occurred in a person with acquired immunodeficiency syndrome (AIDS) and severe immunosuppression to whom MMR vaccine was administered,¹²⁶ and morbidity related to measles vaccination has been reported for people with severe immunosuppression unrelated to HIV infection. The antibody response to measles vaccine in severely immunocompromised HIV-infected people is diminished.⁵⁸

In the United States, the incidence of measles currently is very low. Among HIV-infected people who do not have evidence of severe immunosuppression, no serious or unusual adverse events have been reported after receiving measles vaccination.^{470,512,519,615} MMR vaccination is recommended for all asymptomatic HIV-infected people who do not have evidence of severe immunosuppression and for whom measles vaccination would otherwise be indicated. MMR vaccination also should be considered for all symptomatic HIV-infected people who do not have evidence of severe immunosuppression.⁵⁶⁸ Testing asymptomatic people for HIV is not necessary before administering MMR.¹⁷

Systemically absorbed corticosteroids can suppress the immune system of an otherwise healthy person. However, neither the minimal dose nor the duration of therapy sufficient to cause immune suppression is well defined. Although the immunosuppressive effects of corticosteroid treatment vary, many clinicians consider that a corticosteroid dose equivalent to or greater than a prednisone dose of 2 mg/kg per day or a total of 20 mg/day is sufficiently immunosuppressive to raise concern about the safety of administering live virus vaccines. People who have received systemic corticosteroids in doses of 2 mg/kg per day or 20 mg daily or on alternate days for an interval of 14 days or longer should avoid receiving vaccination with MMR for at least 1 month after cessation of corticosteroid therapy.^{471,568} People who have received prolonged or extensive topical, aerosolized, or other local corticosteroid therapy that causes clinical or laboratory evidence of systemic immunosuppression also should avoid receiving vaccination with MMR for at least 1 month after cessation of therapy.⁴⁷¹

The live attenuated measles virus vaccine used for immunization is not communicable. Contacts of immunocompromised patients should be vaccinated to prevent the spread of natural measles to these patients.

Although no direct evidence has demonstrated that measles vaccine is harmful to a pregnant woman or her fetus, the vaccine should not be administered to women known to be pregnant or who are considering becoming pregnant because of the theoretical risk of fetal infection

TABLE 245.11 Suggested Intervals Between Immune Globulin Administration and Measles or Varicella Vaccination

Product and Indication	Route	DOSE		
		U or mL	mg/kg	Interval (mo) ^a
RSV monoclonal antibody (Synagis)	IM	—	15 (monoclonal)	None
Tetanus (as TIG)	IM	250 U	10	3
Hepatitis A prophylaxis (as IG)				
Contact prophylaxis	IM	0.02 mL/kg	3.3	3
International travel	IM	0.06 mL/kg	10	3
Hepatitis B prophylaxis (as HBIG)	IM	0.06 mL/kg	10	3
Rabies prophylaxis (as RIG)	IM	20 IU/kg	22	4
Varicella prophylaxis (as VariZIG)	IM	125 U/10 kg (maximum, 625 U)	20–40	5
Measles prophylaxis (as IG)				
Standard	IM	0.25 mL/kg	40	5
Immunocompromised contact	IM	0.50 mL/kg	80	6
Botulinum immune globulin Intravenous (human, as BabyBIG)	IV	1.5 mL/kg	75	6
Blood transfusion				
Washed RBCs	IV	10 mL/kg	Negligible	None
RBCs, adenine-saline added	IV	10 mL/kg	10	3
Packed RBCs	IV	10 mL/kg	20–60	5
Whole blood	IV	10 mL/kg	80–100	6
Plasma/platelet products	IV	10 mL/kg	160	7
CMV immune globulin	IV	3 mL/kg	150	6
IGIV				
Replacement therapy for immune deficiencies	IV	—	330–400	8
Therapy for ITP	IV	—	400	8
Varicella prophylaxis	—	—	400	8
Therapy for ITP	IV	—	1000	10
Therapy for ITP or Kawasaki disease	IV	—	1600–2000	11

^aThese intervals should provide sufficient time for decreases in passive antibodies in all children to allow an adequate response to measles or varicella vaccine. Physicians should not assume that children are fully protected against measles during these intervals. Additional doses of immune globulin or measles vaccine may be indicated after exposure to measles. *BabyBIG*, Botulinum immune globulin; *CMV*, cytomegalovirus; *HBIG*, hepatitis B immune globulin; *IG*, immune globulin; *IM*, intramuscular; *ITP*, immune thrombocytopenic purpura; *IV*, intravenous; *IGIV* intravenous immune globulin; *RIG*, rabies immune globulin; *RBCs*, red blood cells; *RSV*, respiratory syncytial virus; *TIG*, tetanus immune globulin; *VariZIG*, varicella-zoster immune globulin.

In: Kimberlin DW, Brady MT, Jackson MA, Long SS, editors. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. pp. 38–40, Elk Grove Village, IL: American Academy of Pediatrics; 2015 and Kroger A, Sumaya C, Pickering L, et al. General recommendations on immunization—recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2011;60:1–64.

associated with a live virus vaccine. Women vaccinated with MMR should avoid conception for 28 days after being vaccinated.¹³⁹

Because measles vaccination may diminish cutaneous manifestations of cell-mediated immunity temporarily, a tuberculin test performed several days to 6 weeks after receiving immunization can yield a false-negative result. Although natural measles infection can exacerbate tuberculosis, no evidence indicates that measles vaccination is associated with such an effect. Tuberculin skin testing is not a prerequisite for administering measles immunization. If a tuberculin test is indicated, it should be performed on the day of immunization or postponed for 4 to 6 weeks because measles vaccination may suppress tuberculin reactivity temporarily.

For people who are allergic to eggs, the risk of having serious allergic reactions such as anaphylaxis after receiving MMR vaccine is extremely low, and skin testing with vaccine cannot predict an allergic reaction to vaccination.^{38,369,386} Obtaining a skin test is not required before administering MMR to people who are allergic to eggs. Similarly, the administration of gradually increasing doses of vaccine is not required.⁴⁷¹ Data indicate that most anaphylactic reactions to measles- and mumps-containing vaccines are not associated with hypersensitivity to egg antigens but rather to other components of the vaccines, such as the gelatin stabilizer.^{311,340,385,419}

Children with a history of thrombocytopenic purpura or thrombocytopenia may be at risk for clinically significant thrombocytopenia after receiving immunization with MMR.^{70,362} The decision to vaccinate should be based on the benefits of immunity to measles, mumps, and rubella and the risk of recurrence or exacerbation of the

thrombocytopenia after receiving vaccination or from natural infection with measles or rubella. For children in whom thrombocytopenia develops in the month after receiving a dose of measles-containing vaccine, withholding the second dose of measles vaccine is prudent if the incidence of measles remains low.

Receipt of antibody-containing blood products (i.e., whole blood, plasma, or parenteral immune globulin) may interfere with seroconversion in response to the measles vaccine. High doses of immune globulin preparations can inhibit the immune response to measles vaccine for 3 or more months, depending on the dosage.⁶⁰³ The length of time that passively acquired antibody persists depends on the concentration and quantity of the blood product received (Table 245.11).^{38,471}

As with any condition that induces fever during the second year of life, children predisposed to having febrile seizures may experience seizures after receiving measles vaccination. Most convulsions that develop after receiving measles immunization are simple febrile seizures and occur in children without known risk factors. Febrile seizures that occur after the administration of vaccinations do not increase the risk of epilepsy or other neurologic disorders.⁶⁶ The risk of seizures after receiving measles vaccination may be increased for children with a history of convulsions or those with a history of convulsions in first-degree family members.⁶⁶² Although the exact risk cannot be determined, it appears to be low. The recommendation to immunize children with a personal history of seizures or those with a history of seizures in first-degree family members is based on factors indicating that the benefits greatly outweigh the risks. Prophylactic use of anticonvulsants usually is not feasible because therapeutic concentrations of many

currently prescribed anticonvulsants are not achieved for some time after the initiation of therapy.

Meningococcal Vaccine

N. meningitidis causes a spectrum of infections, including meningitis, bacteremia, and rarely bacteremic pneumonia. Meningococcal disease develops rapidly and is fatal in 10% to 15% of cases. Of patients who recover, 11% to 19% have permanent hearing loss, neurologic disability, loss of limbs, or other serious sequelae.

In the United States since the introduction of Hib and pneumococcal polysaccharide-protein conjugate vaccines for infants, *N. meningitidis* has become the leading cause of bacterial meningitis in children and remains an important cause of bacteremia and sepsis.^{586,686} Disease most often occurs in previously healthy children 2 years or younger; the peak incidence occurs among children younger than 1 year.⁴⁴² Another peak occurs among adolescents and young adults 16 through 21 years of age. Historically, college freshman who lived in dormitories and military recruits in boot camp had a higher rate of disease compared with people who are the same age and who are not living in such accommodations.

Close contacts of patients with meningococcal disease are at increased risk for infection. The attack rate for household contacts is 500 to 800 times the rate in the general population. Patients with persistent complement component deficiencies (i.e., C5 to C9, properdin, or factor H or factor D deficiencies) or anatomic or functional asplenia are at increased risk for invasive and recurrent meningococcal disease. Although surveillance data for cases of meningococcal disease among HIV-infected persons are limited in the United States, a growing body of evidence demonstrates an increased risk of meningococcal disease among HIV-infected people.⁴⁴⁵

There are 12 known serogroups of *N. meningitidis*. Six serogroups (i.e., A, B, C, W, X, and Y) are responsible for invasive human disease. Serogroups A and X are rare in the United States. Distribution of the other serogroups in the United States has shifted in the past 2 decades.²⁰⁵ Serogroups B, C, and Y each account for approximately 30% of reported cases. Approximately three fourths of cases among adolescents and young adults are caused by serogroups C, Y, or W135. Among infants, 50% to 60% of cases are caused by serogroup B.

For unknown reasons, the incidence of meningococcal disease has declined since the peak of disease in the late 1990s.²⁰⁵ Approximately 800 to 1200 cases are reported annually in the United States. The decline began before the implementation of routine adolescent conjugate polysaccharide meningococcal immunization and has occurred in all serogroups, including those not included in the available vaccines.

In the United States, the incidences of serogroups C and Y, which represent most cases of meningococcal disease, are at historic lows. However, a peak in disease incidence among adolescents and young adults 16 to 21 years of age has persisted, even after routine vaccination of adolescents was recommended in 2005. From 2006 through 2010, the first 5 years after routine use of meningococcal vaccine was recommended, the CDC received reports of approximately 30 cases of serogroup C and Y meningococcal disease among people who had received the vaccine. The case-fatality ratio was similar among people who had received vaccine compared with those who were unvaccinated. Of the 13 reports of breakthrough disease for which data on underlying conditions were available, four people had underlying conditions or behaviors associated with an increased risk of bacterial infections, including type 1 diabetes mellitus, current smoking, history of bacterial meningitis and recurrent infections, and aplastic anemia, paroxysmal nocturnal hemoglobinuria, and receipt of eculizumab, an immune modulator that blocks complement protein C5.⁴⁴³

Serogroup B disease incidence has declined despite the fact that serogroup B is not contained in any of the existing conjugate polysaccharide meningococcal vaccines. Approximately 50 to 60 cases of serogroup B meningococcal disease occur annually among adolescents and young adults 11 through 24 years of age in the United States.²⁰⁵

Outbreaks occur in communities and institutions, including childcare centers, schools, colleges, and military recruit camps. In the United States, approximately 98% of cases of meningococcal disease are sporadic; however, outbreaks of meningococcal disease continue to occur.⁹³ From

2009 through 2015, there were seven outbreaks of serogroup B meningitis at US universities that resulted in 43 cases and 3 deaths.

In other parts of the world, the number of cases is much higher.³⁶⁸ In the sub-Saharan African meningitis belt, which extends from Ethiopia to Senegal, peaks of serogroup A meningococcal disease occur regularly during the dry season. Major epidemics occur every 8 to 12 years. In each epidemic, tens of thousands of cases and thousands of deaths can occur. Approximately 350 million people are at risk. The phased introduction of MenAfriVac, a novel serogroup A meningococcal conjugate vaccine that is being implemented through preventive national campaigns in meningitis belt countries for all individuals 1 to 29 years of age, holds great promise to end epidemic meningitis.⁴⁰⁶

Meningococcal disease continues to cause epidemics outside the meningitis belt.³⁶⁸ Serogroup W135 has emerged as an epidemic strain causing disease in Saudi Arabia in association with the Hajj pilgrimage. Since 2002, serogroup W meningococcal disease has also been reported in sub-Saharan African countries during epidemic seasons. More recently, serogroup W outbreaks have occurred in South America. Serogroup X, previously a rare cause of sporadic meningitis, has been responsible for outbreaks between 2006 and 2010 in Kenya, Niger, Togo, Uganda, and Burkina Faso.⁷⁰⁵ Prolonged outbreaks of serogroup B meningococcal disease have occurred in New Zealand, France, and Oregon. Serogroup Y emerged in Colombia and Venezuela, where it became the common disease-causing serogroup in 2006.⁵⁷¹

Preparations

MenACWY vaccines. Four meningococcal vaccines that contain purified capsular polysaccharide alone or that are conjugated to a carrier protein are licensed and available in the United States for the prevention of invasive disease caused by *N. meningitidis* serogroups A, C, W135, and Y (Table 245.12).

Quadrivalent meningococcal polysaccharide vaccine (MPSV4; Menomune, Sanofi Pasteur) was licensed in 1981 for use in children 2 years or older. Each vaccine dose contains 50 mg of each of the four purified bacterial capsular polysaccharides from serogroups A, C, Y, and W135. MPSV4 is available as a single dose or multidose (10-dose) vial of lyophilized vaccine, with a corresponding single-dose or multidose vial of diluent. After reconstitution of the lyophilized vaccine with the diluent, each dose consists of a 0.5-mL solution for injection. Vaccine supplied in single-dose vials should be used immediately after reconstitution. Vaccine supplied in multidose vials may be used for up to 35 days after reconstitution if stored at 2°C to 28°C (35°F–46°F). MPSV4 is administered subcutaneously and can be given concurrently with other vaccines but at different anatomic sites.

Two meningococcal conjugate vaccines (i.e., MenACWY-D [Menactra, Sanofi Pasteur] and MenACWY-CRM [Menveo, Novartis Vaccines]) are licensed for use in people 2 through 55 years of age. MenACWY-D is a liquid solution supplied in 0.5-mL single-dose vials. Each dose contains 4 µg each of the four capsular polysaccharides from serogroups A, C, Y, and W135 conjugated to 48 µg of diphtheria toxoid. MenACWY-CRM consists of two components: 10 µg of lyophilized meningococcal serogroup A capsular polysaccharide conjugated to CRM197 (MenA) and 5 µg each of capsular polysaccharide of serogroup C, Y, and W135 conjugated to CRM197 in 0.5 mL of phosphate buffered saline, which is used to reconstitute the lyophilized MenA component before injection. The reconstituted vaccine should be used immediately but may be held at or below 25°C (77°F) for up to 8 hours. Meningococcal conjugate vaccines are administered intramuscularly as a single 0.5-mL dose and can be given concurrently with other recommended vaccines. Limited data suggest that different conjugate vaccine products can be used interchangeably.²⁰⁴

MenACWY-D and MenACWY-CRM are also licensed for infants but with different administration schedules. MenACWY-D is licensed as a two-dose primary series, 3 months apart, for children 9 through 23 months of age. MenACWY-CRM is licensed for use in children 2 through 23 months of age. For children initiating vaccination at 2 months of age, MenACWY-CRM is administered as a four-dose series at 2, 4, 6, and 12 months of age. For children initiating vaccination at 7 months through 23 months of age, MenACWY-CRM is administered as a two-dose series with the second dose administered in the second year of life and at least 3 months after the first dose.

TABLE 245.12 Licensed Meningococcal Vaccines—United States, 1981–2015

Formulation	Type	Trade Name	Manufacturer	Licensed (y)	Age Group	Doses	Serogroups
MPSV4 ^a	Polysaccharide	Menomune	Sanofi Pasteur	1981	≥2 y	Single dose	A, C, W, and Y
MenACWY-D ^b	Conjugate	Menactra	Sanofi Pasteur	2005	11–55 y	Single dose	A, C, W, and Y
MenACWY-D ^b	Conjugate	Menactra	Sanofi Pasteur	2007	2–10 y	Single dose	A, C, W, and Y
MenACWY-D ^b	Conjugate	Menactra	Sanofi Pasteur	2011	9–23 mo	2-dose series	A, C, W, and Y

In June 2012, a combination conjugate vaccine against Hib (i.e., PRP-T) and *N. meningitidis* serogroups C and Y (i.e., Hib-MenCY-TT [MenHibrix, GlaxoSmithKline]) was licensed. Hib-MenCY-TT contains 5 µg of *N. meningitidis* serogroup C capsular polysaccharide, 5 µg of *N. meningitidis* serogroup Y capsular polysaccharide, and 2.5 µg of *Haemophilus influenzae* serogroup B capsular polysaccharide, with each conjugated to tetanus toxoid. The vaccine is lyophilized and should be reconstituted with a 0.9% saline diluent. After reconstitution of the lyophilized vaccine with the diluent, each dose consists of a 0.5-mL solution for injection. Hib-MenCY-TT is administered intramuscularly and is approved as a four-dose series for children at 2, 4, 6, and 12 through 18 months.

MenB vaccines. In October 2014, the first serogroup B meningococcal vaccine, MenB-FHbp (Trumenba, Wyeth Pharmaceuticals) was licensed. A second serogroup B vaccine, MenB-4C (Bexero, Novartis Vaccines), was licensed in January 2015 (see Table 245.12). Both vaccines are licensed for use in people 10 through 25 years of age.

MenB-FHbp is a bivalent vaccine consisting of two recombinant lipidated factor H binding protein (FHbp) antigens, one from FHbp subfamily A and one from subfamily B. FHbp is one of many proteins found on the surface of meningococci and contributes to the ability of the bacterium to avoid host defenses. The FHbp proteins are individually produced in *Escherichia coli*. Each 0.5-mL dose contains 60 µg of each FHbp variant, 0.018 mg of polysorbate 80, and 0.25 mg of Al³⁺ as AlPO₄ in 10 mM histidine buffered saline at pH 6.0. The vaccine is administered as a 0.5-mL dose intramuscularly. MenB-FHbp is licensed as for a three-dose series and a two-dose series. In April 2016, the FDA approved a label change giving MenB-FHbp a flexible three-dose schedule of 0, 1 to 2 months, and 6 months and a two-dose schedule of 0 and 6 months.

MenB-4C is a multicomponent vaccine consisting of three recombinant proteins (i.e., neisserial adhesion A [NadA], factor H binding protein [FHbp] fusion protein, and neisserial heparin binding antigen [NHBA] fusion protein) and outer membrane vesicles (OMVs) containing outer membrane protein PorA serosubtype P1.4 (i.e., New Zealand epidemic strain NZ98/254). The three recombinant proteins are individually produced in *E. coli*. The OMV antigenic component is produced by fermentation of *N. meningitidis* strain NZ98/254 (expressing outer membrane protein PorA serosubtype P1.4), followed by inactivation of the bacteria by deoxycholate, which also mediates vesicle formation. The antigens are adsorbed onto aluminum hydroxide. Each 0.5-mL dose of MenB-4C contains 50 µg each of recombinant proteins NadA, NHBA, and FHbp; 25 µg of OMV; 1.5 mg of aluminum hydroxide (0.519 mg of Al³⁺), 3.125 mg of sodium chloride; 0.776 mg of histidine; and 10 mg of sucrose at pH 6.4 to 6.7. The vaccine is administered as a 0.5-mL dose intramuscularly.

MenB-4C is licensed as a two-dose series, with doses administered at least 1 month apart.

Immunogenicity and Efficacy

MenACWY vaccines. The polysaccharide capsule of *N. meningitidis* is an important determinant of virulence. Serum antibody to capsular polysaccharide protects against disease by activating complement-mediated bacteriolysis or opsonization, or both. Complement-dependent bactericidal activity induced by immunization with meningococcal vaccine is measured by use of a serum bactericidal antibody assay with a human (hSBA) complement source. A defined bactericidal antibody titer that indicates protection against invasive meningococcal disease is assay dependent. When sera are tested using a human complement source, SBA titers of 1:4 or higher are considered protective. Studies have demonstrated that almost all people who developed invasive serogroup C meningococcal disease had sera that lacked bactericidal activity to the pathogenic meningococcal strain.^{304,307} In contrast, people with detectable SBA against a specific strain rarely developed disease.

The characteristics of MPSV4 are similar to other polysaccharide vaccines (e.g., pneumococcal polysaccharide). The vaccine is usually not effective in children younger than 18 months. The response to the vaccine is typical of a T-cell independent antigen, with an age-dependent response and poor immunogenicity in children younger than 2 years. Little boost in antibody titer occurs with repeated doses; the antibody that is produced is relatively low-affinity IgM, and switching from IgM to IgG production is poor.

Protective antibody concentrations are achieved within 10 to 14 days of administration of MPSV4. The vaccine elicits protective levels of bactericidal antibody to all four serogroups in more than 97% of recipients as measured at 28 days after vaccination. The antibody responses to each of the four polysaccharides in the polysaccharide vaccine are serogroup specific and independent. Group A polysaccharide induces antibody in some children as young as 3 months, although a response comparable to that in adults is not achieved until the child is 4 to 5 years of age.⁵³¹ The serum antibody response to serogroup C is age dependent, with a poor response in children younger than 2 years.³⁰³ Serum concentrations of antibodies against group A and C polysaccharides decrease markedly during the first 3 years after receipt of a single dose of vaccine. The decrease in antibody occurs more rapidly in infants and young children than in adults.^{384,712}

Field trials of A and C meningococcal vaccines in Europe and Africa have demonstrated efficacy rates against serogroup A of 85% to 95% 1 year after vaccination.^{531,667} After 3 years, efficacy rates were 67% for older children but only 10% for children younger than 4 years at the time of immunization with serogroup A vaccine.⁵⁵³ In an epidemic,

serogroup C vaccine demonstrated clinical efficacy rates similar to those for the serogroup A vaccine.⁶³³

Serogroup Y and W135 antigens are immunogenic and safe in children older than 2 years. However, clinical efficacy has not been demonstrated for these preparations.^{12,57,664}

People with deficiencies of the terminal components of serum complement and those with anatomic or functional asplenia have antibody responses to quadrivalent meningococcal vaccines consistent with protection.^{565,567} However, the clinical efficacy of vaccination has not been evaluated in these people.

Meningococcal conjugate vaccines prime the immune system, and immunologic memory persists even in the absence of detectable bactericidal antibodies. Although vaccine-induced immunologic memory often protects against infection with other encapsulated bacteria such as Hib, detectable circulating antibody appears to be important for protection against *N. meningitidis*.³⁰⁴ Effectiveness of the three meningococcal conjugate vaccines, which were licensed after MPSV4, was inferred by comparing SBA responses induced by the new vaccines compared with SBA responses induced by MPSV4 in people 2 through 55 years of age or by achieving a seroresponse at or above a predefined bactericidal antibody titer among children 2 through 23 months of age.

Protective antibody concentrations are achieved within 8 days after administration of MenACWY-D.⁷⁸ In studies conducted among people 11 to 55 years of age comparing the immunogenicity of conjugate vaccine with that of the polysaccharide vaccine at 28 days after vaccination, the percentage of those achieving at least a fourfold increase in bactericidal titer for each serogroup was higher in the MPSV4 group than in the MenACWY-D group for people older than 18 years. Nonetheless, the criteria for demonstrating immunologic noninferiority to MPSV4 were still achieved. The percentage of those with at least a fourfold rise was highest for serogroup W135 and lowest for serogroup Y. The percentage of people achieving a protective level of bactericidal antibody was greater than 97% for all serogroups in the MenACWY-D and MPSV4 groups.

Response to revaccination with MenACWY-D was assessed by administering MenACWY-D to people previously vaccinated with MPSV4 or MenACWY-D and to vaccine-naïve control subjects. All people in all three groups achieved protective bactericidal antibody titers at 8 and 28 days after receiving MenACWY-D. Those initially primed with MenACWY-D achieved higher bactericidal antibody concentrations than those of the naïve controls for all serogroups except A. In contrast, bactericidal antibody titers of those primed with MPSV4 were lower than those of vaccine-naïve controls on days 8 and 28 for all serogroups.

In study participants 11 to 18 years of age, noninferiority of MenACWY-CRM to MenACWY-D was demonstrated for all four serogroups.¹⁶⁶ The proportions of people with seroresponses were statistically higher for serogroups A, W, and Y in the MenACWY-CRM group, compared with the MenACWY-D group. The clinical relevance of higher postvaccination immune responses is not known.

The immunogenicity of MenACWY-CRM in children 2 through 10 years of age was evaluated in a multicenter, randomized, controlled trial.³²⁷ After a single MenACWY-CRM dose, seroresponses to group C, Y, and W135 in children 2 through 5 years and 6 through 10 years of age were noninferior to responses after a single MenACWY-D dose.

MPSV4 is administered subcutaneously, whereas MCV4 is administered intramuscularly. More than 100 people have inadvertently received the MCV4 vaccine by the subcutaneous route. For a subset of these individuals, the CDC determined that although the serologic responses were lower after MCV4 was administered subcutaneously compared with intramuscularly, the proportions of individuals who achieved antibody levels thought to be protective were similar. The CDC therefore did not recommend that those who had received MCV4 needed to be reimmunized.¹⁴⁹

In clinical trials Hib-MenCY-TT was coadministered with DTaP-HepB-IPV and 7-valent pneumococcal conjugate vaccine (PCV7) at ages 2, 4, and 6 months and with MMR, varicella, and PCV7 vaccines at 12 to 15 months of age. No decreased immunogenicity of coadministered vaccines was observed.^{96,460} A randomized, controlled, multicenter study evaluated the percentage of subjects with hSBA titers of 1:8 or higher at 2 months after the second dose was administered at 4 months of age. In the group vaccinated with Hib-MenCY-TT, 94% and 83% of

children achieved hSBA antibody titers of 1:8 or higher for meningococcal serogroups C and Y, respectively, after the second dose.⁵⁰⁷

When the MenACWY-D vaccine was licensed in 2005, some experts predicted that the vaccine would be effective for up to 10 years, providing protection through the period of highest risk in late adolescence and early adulthood. Since the 2005 ACIP recommendations, additional data have improved our understanding of meningococcal conjugate vaccines, including the duration of vaccine-induced immunity. Antibody persistence studies indicate that circulating antibody declines 3 to 5 years after a single dose of MenACWY-D or MenACWY-CRM.^{296,388,665} Results from a vaccine effectiveness study demonstrate waning effectiveness, and many adolescents are not protected 5 years after vaccination.²⁰³ ACIP concluded that a single dose of meningococcal conjugate vaccine administered at age 11 or 12 years is unlikely to protect most adolescents through the period of increased risk at ages 16 through 21 years. On the basis of this information, in 2011, ACIP recommended adding a booster dose at 16 years of age.¹⁶⁹

MenB vaccine. The immunogenicity of both serogroup B meningococcal vaccines (i.e., MenB-4C and MenBFHbp) has been evaluated in numerous published clinical trials.^{391,461,546,556,576,575,591,640} Both vaccines appear to provide short-term immunogenicity in healthy populations. Studies on vaccine efficacy are not available. Licensure was based on the ability of the vaccines to elicit detection of bactericidal antibody that is presumed to indicate protection. Studies regarding antibody persistence are limited. Immunogenicity studies in populations at increased risk for invasive meningococcal disease have not been completed.

MenB-FHbp has been administered concomitantly with the following: quadrivalent human papillomavirus (HPV) vaccine³⁹¹ but not 9-valent HPV vaccine, with MenACWY (unpublished data), and with Tdap vaccine (Adacel, Sanofi Pasteur [unpublished data]).

Adverse Events

MenACWY vaccines. MPSV4 has been used extensively in mass-immunization programs and in the military and among international travelers. Adverse reactions to MPSV4 usually are mild; the most frequent reactions are pain and redness at the injection site that last for 1 or 2 days.⁶² Estimates of the incidence of local reactions range from 4% to 56%. Transient fever occurs in as many as 5% of vaccine recipients in some studies but is less common in older children and adults.

The most frequently reported adverse events reported to VAERS for MenACWY-D include fever (16.8%), headache (16.0%) injection-site erythema (14.6%), and dizziness (13.4%). Syncope has been identified as an adverse event after any vaccination, with a higher proportion of syncope events reported to VAERS occurring in adolescents than other age groups.¹⁵⁴ Syncope was listed in 10% of reports involving MenACWY-D. Twenty-four deaths (0.3%) were reported.

The most frequently reported adverse events for MenACWY-CRM were injection-site erythema (19.7%) and injection site swelling (13.7%). Syncope was listed in 8.8% of reports involving MenACWY-CRM. One death (0.4%) was reported.

Rates of local and systemic adverse events observed after administration of Hib-MenCY-TT were comparable to rates observed after administration of Hib-TT. Hib-MenCY-TT was found to be safe and immunogenic for Hib and meningococcal serogroups C and Y.

MenB vaccine. The safety of both serogroup B meningococcal vaccines (i.e., MenB-4C and MenBFHbp) have been evaluated in numerous published clinical trials.^{391,461,556,575,591,597} There were no deaths considered to be related to either vaccine. The most frequently reported severe local and systemic adverse events for MenB-4C include injection site pain (20–29%), fever of 38°C or higher (1–5%), headache (4–6%), fatigue (4–6%), myalgias (12–13%), and joint pain (2%). For MenBFHbp, the most frequently reported severe local and systemic adverse events include injection site pain (5–8%), fever of 38°C (2–8%), headache (1%), fatigue (1–4%), myalgias (1–3%), and joint pain (1%).

Indications

Meningococcal polysaccharide vaccine. Routine vaccination of civilians with MPSV4 is not recommended.²⁰⁴ Use of MPSV4 should be limited to people older than 55 years or when MenACWY is not available.

TABLE 245.13 Recommended Meningococcal Vaccines for Immunocompetent Children

Age	Vaccine	Status
2 mo–10 y	MenACWY-D ^a MenACWY-CRM ^b HibMenCY-TT ^c	Not routinely recommended
10–25 y	MenB-FHbp or MenB-4C	Not routinely recommended
11–21 y	MenACWY-D or MenACWY-CRM	Primary: Age 11–12 y: 1 dose Age 13–18 y: 1 dose if not previously immunized Age 19–21 y: not routinely recommended but may be given as catch-up immunization for those who have not received a dose after their 16th birthday Booster: 1 dose recommended for adolescents if first dose administered before 16th birthday

^aLicensed only for people 9 mo to 55 y.

^bLicensed only for people 2 mo to 55 y.

^cLicensed only for children 6 wk to 18 mo.

Modified from American Academy of Pediatrics. Meningococcal infections. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:547–58.

Meningococcal conjugate vaccines. Routine childhood immunization with meningococcal conjugate vaccine (i.e., MenACWY) is recommended for adolescents 11 through 18 years of age, but it is not recommended for children 2 months through 10 years of age because the infection rate is low for this age group; the immune response is less robust than in older children, adolescents, and adults; and duration of immunity is unknown.^{28,39,204} Recommendations for routine use of MenACWY in adolescents are shown in [Table 245.13](#) and are as follows:^{28,39,204}

- Adolescents should be immunized routinely at the 11- to 12-year of age health care visit, when immunization status and other preventive health services can be addressed. A booster dose at 16 years of age is recommended for adolescents immunized at 11 through 12 years of age.
- Adolescents 13 through 18 years of age should be immunized routinely with a meningococcal conjugate vaccine if not previously immunized. Adolescents who receive the first dose at 13 through 15 years of age should receive a one-time booster dose at 16 through 18 years of age.
- Adolescents who receive their first dose of meningococcal conjugate vaccine at or after 16 years of age do not need a booster dose unless they have risk factors.
- People 19 to 21 years of age are not routinely recommended to receive meningococcal conjugate vaccine, but vaccine may be administered as a catch-up dose for those who have not received a dose after their 16th birthday.

The ACIP and the AAP recommend routine use of meningococcal conjugate vaccines (e.g., MenACWY) for people 2 months or older who have certain medical conditions that increase the risk of meningococcal disease, including those who have persistent (e.g., genetic) deficiencies in the complement pathway (e.g., C3, properdin, factor D, factor H, C5–C9), people receiving eculizumab (because the drug binds C5 and inhibits the terminal complement pathway), and people with functional or anatomic asplenia, including people with sickle cell disease ([Table 245.14](#)).^{28,39,204} In 2016, the ACIP recommended that people 2 months or older with HIV infection also be given meningococcal conjugate vaccines based on data indicating an increased risk of disease.⁴⁴⁵ Specific recommendations for immunization of high-risk

TABLE 245.14 Meningococcal Vaccine Recommendations by Risk Group

MenACWY Vaccines	MenB Vaccines

^aInherited or chronic deficiencies of C3, C5–C9, properdin, factor D, or factor H or those receiving eculizumab.

^bIncludes sickle cell disease.

^cThe CDC defines outbreaks and those at risk.

^dOnly microbiologists who routinely work with *N meningitidis*.

^eTo areas with hyperendemic or epidemic meningococcal disease.

^fUnvaccinated or inadequately vaccinated first-year college students who live in residence halls.

Modified from Committee on Infectious Diseases, American Academy of Pediatrics. Recommendations for serogroup B meningococcal vaccine for persons 10 years and older. *Pediatrics*. 2016;138:e20161890.

children with meningococcal conjugate vaccines are shown in [Table 245.15](#).^{28,39,204,445}

MenB vaccines. Routine vaccination with meningococcal serogroup B vaccine is recommended for those 10 years or older who are at increased risk for serogroup B disease (see [Tables 245.14](#) and [245.15](#)), including the following groups: (1) people with persistent complement component diseases, including inherited or chronic deficiencies in C3, C5–C9, properdin, factor D, or factor H, and people receiving eculizumab; (2) people with anatomic or functional asplenia, including sickle cell disease; and (3) healthy people who are at increased risk because of a serogroup B meningococcal disease outbreak.^{211,276,444} The AAP and the CDC do not express a preference for the two licensed vaccines, but the same product must be used for the entire series.

A three-dose schedule for MenB-FHbp is recommended for people at increased risk for meningococcal serogroup B disease. For healthy people 16 to 23 years of age who are not at increased risk for meningococcal serogroup B disease, the ACIP has a permissive recommendation that allows use of one of the meningococcal serogroup B vaccines if the patient desires to be immunized.^{211,444} If an adolescent so chooses and MenB-FHbp is selected, the ACIP recommends a two-dose schedule. If a patient receives a second dose of MenB-FHbp less than 6 months after the first dose, a third dose should be given at least 6 months after the first.

Postexposure Immunoprophylaxis

Because secondary cases can occur several weeks or more after onset of disease in the index case, meningococcal vaccine is an adjunct to chemoprophylaxis when an outbreak is caused by a serogroup prevented by a meningococcal vaccine. For control of meningococcal outbreaks caused by vaccine-preventable serogroups (i.e., A, C, Y, and W135), the preferred vaccine for adults and children 2 years and older is a meningococcal conjugate vaccine (i.e., MenACWY).²⁰⁴ For outbreaks caused by serogroup B meningococcal disease, vaccination with a serogroup B meningococcal vaccine is recommended for those 10 years or older identified as being at increased risk because of the outbreak.¹⁷⁸

Precautions and Contraindications

Vaccination with MenACWY, MPSV4, or Hib-MenCY-TT is contraindicated for people known to have a severe allergic reaction to any component of the vaccine, including diphtheria or tetanus toxoid. The ACIP does not consider a history of Guillain-Barré syndrome to be a contraindication or precaution for meningococcal vaccination.²⁰⁴ Because MenACWY, MPSV4, and Hib-MenCY-TT are inactivated vaccines, they can be administered to people who are immunosuppressed as a result

TABLE 245.15 Recommended Immunization Schedule and Intervals for Children at Risk for Invasive Meningococcal Disease^a

Age	Subgroup	Primary Immunization	Booster Dose ^b
2–18 mo ^c	Children who have persistent complement deficiencies, have functional or anatomic asplenia are at risk during a community outbreak attributable to a vaccine serogroup	4 doses of HibMenCY-TT at 2, 4, 6, and 12–15 mo ^c	Person remains at increased risk and first dose received at following age: For 2 mo–6 y of age: should receive additional dose of MenACWY 3 y after primary immunization; boosters should be repeated every 5 y thereafter For ≥7 y of age: should receive additional dose of MenACWY 5 y after primary immunization; boosters should be repeated every 5 y thereafter
2–23 mo with high-risk conditions	Children who have persistent complement deficiencies, have functional or anatomic asplenia, have HIV, travel to or are residents of countries where meningococcal disease is hyperendemic or epidemic are at risk during a community outbreak attributable to a vaccine serogroup	4 doses of MenACWY-CRM (Menveo) at 2, 4, 6, and 12 mo	
9–23 mo with high-risk conditions	Children who have persistent complement deficiencies, travel to or are residents of countries where meningococcal disease is hyperendemic or epidemic are at risk during a community outbreak attributable to a vaccine serogroup	2 doses of MenACWY (Menactra), 12 wk apart ^d	
2–55 y with high-risk conditions and not immunized previously ^{e,f}	People who have persistent complement deficiencies, have functional or anatomic asplenia, have HIV People who travel to or are residents of countries where meningococcal disease is hyperendemic or epidemic are at risk during a community outbreak attributable to a vaccine serogroup	2 doses of MenACWY, 8–12 wk apart 1 dose of MenACWY ^e	
≥10 y with high-risk conditions	People who have persistent complement deficiencies, have functional or anatomic asplenia are at risk during a community outbreak attributable to a vaccine serogroup	2 doses of MenB-4C 4 wk apart or 3 doses of MenB-FHbp administered at 0, 2 and 6 mo	—

^aIncludes children who have persistent complement deficiencies (e.g., C5–C9, properdin, factor H or factor D) and anatomic or functional asplenia; travelers to or residents of countries in which meningococcal disease is hyperendemic or epidemic; and children who are part of a community outbreak of a vaccine-preventable serogroup.

^bIf child remains at increased risk of meningococcal disease.

^cInfants and children who received Hib-MenCY-TT and are traveling to areas with highly endemic rates of meningococcal disease, such as the African “meningitis belt,” are not protected against serogroups A and W and should receive a quadrivalent meningococcal vaccine licensed for children age ≥2 mo before travel.

^dBecause of high risk of invasive pneumococcal disease, children with functional or anatomic asplenia should not be immunized with MenACWY-D (Menactra) before age 2 y to avoid interference with the immune response to the pneumococcal conjugate vaccine (PCV) series.

^eIf MenACWY-D is used, administer at least 4 weeks after completion of all PCV doses.

^fIf an infant is receiving the vaccine before travel, two doses can be administered as early as 2 months apart.

Modified from American Academy of Pediatrics. Meningococcal Infections. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:547–58.

of disease or medications; however, response to the vaccine may be less than optimal.

No RCTs have been conducted primarily to evaluate use of MPSV4 or MenACWY vaccines in pregnant or lactating women. VAERS reports of exposure to MPSV4 during pregnancy have not identified adverse effects among pregnant women or newborns of women vaccinated during pregnancy. From the VAERS reports available for women found to be pregnant at the time of MenACWY-D vaccination, no major safety concerns associated with vaccination have been identified in the mother or fetus. Pregnancy should not preclude vaccination with MenACWY or MPSV4, if indicated.²⁰⁴ Women of childbearing age who become aware that they were pregnant at the time of MenACWY vaccination should contact their health care provider or the vaccine manufacturer so that their experience can be captured in the manufacturer’s registry of vaccination during pregnancy.

Before administering MenB vaccines, treating clinicians should consult the package insert for a full list of precautions, warnings, and contraindications.^{211,444} Pregnancy and breastfeeding are precautions because neither vaccine has been evaluated in these situations. A severe allergic reaction to a previous dose of MenB vaccine or any of its components is a contradiction.

Mumps Vaccine

Live virus mumps vaccine became available in the United States in 1967 and was recommended for routine use in 1977. The incidence of reported mumps cases decreased rapidly after vaccine licensure until 1986 through 1987, when a resurgence of mumps occurred resulting in 20,638 reported

cases.^{111,199} The resurgence was attributed to a susceptible cohort of adolescents and young adults entering high school and college who were not targeted for vaccination and spared from natural infection by declining disease rates. In 1989, the ACIP and AAP implemented a two-dose combined MMR schedule given at 4 to 6 or at 11 to 12 years of age.¹¹⁰ By the early 2000s, on average, fewer than 270 cases were reported annually, and seasonal peaks were no longer seen.⁶⁷

Before vaccine licensure in 1967 and during the early years of vaccine use, most reported cases occurred in the 5- to 9-year age group, with 90% of cases occurring among children 15 years of age and younger. In the late 1980s, a shift toward older children occurred. Since 1990, people 15 years or older have accounted for 30% to 40% of cases per year.

In 2006, an outbreak of 6584 cases occurred and was centered on highly two-dose vaccinated college students in the American Midwest.²²⁹ The 2006 outbreak underscored limitations in the 1998 recommendations about prevention of mumps transmission in health care and other settings with a high risk of mumps transmission. After reviewing data from this outbreak and previous evidence of mumps vaccine effectiveness and transmission, the ACIP issued updated recommendations, specifying that all children and adults in certain high-risk groups, including students at post-high school educational institutions, health care personnel, and international travelers, should receive two doses of mumps-containing vaccine.¹¹⁰ In the next 2 years, the number of reported cases returned to usual levels, and outbreaks involved fewer than 20 cases.

Outbreaks have continued to occur, particularly in high-density, close-contact settings, despite high two-dose coverage. Because two

doses of mumps-containing vaccine are not 100% effective, most mumps cases in settings of high immunization coverage such as the United States most often occur among people who have received two doses. In the 2009–10 season, a large outbreak occurred in the northeastern United States, affecting more than 3500 people, primarily members of traditional observant communities in New York and New Jersey.¹⁶³ There was also an outbreak in the US territory of Guam, with 505 cases reported.⁵⁰⁰ Most patients had received two doses of MMR vaccine and were exposed in communal settings. In 2011 through 2013, there were several smaller mumps outbreaks reported on college campuses in California,¹⁷³ Virginia, and Maryland. However, they had limited spread, and national case counts for these years were at several hundred cases per year.

In 2014, several outbreaks affiliated with universities were reported from multiple states, including one community outbreak in Ohio linked to a university that involved over 400 people and an outbreak affecting the National Hockey League. Outbreaks have been reported from several university campuses in 2015 through 2016, including a number of smaller outbreaks with limited spread. The two largest outbreaks were from Iowa and Illinois, each involving several hundred university students; both held wide-scale vaccination campaigns that included providing a third dose of MMR as a control measure.⁷

In 2016, the greatest number of mumps cases since the outbreaks of 2006 was reported. These outbreaks involved 45 states and more than 2800 individuals. Six states (i.e., Arkansas, Illinois, Indiana, Iowa, Massachusetts, and Oklahoma) reported more than 100 cases in 2016.

Preparations

The live attenuated mumps virus vaccine (i.e., Jeryl Lynn strain) used in the United States is prepared in chick embryo cell culture and is available in combination as MMR and MMRV. The AAP and ACIP recommend that combined MMR vaccine be used when any of the individual components is indicated, and MMRV is recommended if the vaccinee is 12 months through 12 years of age.

Each dose of vaccine contains neomycin, sorbitol, and hydrolyzed gelatin as stabilizers. Before reconstitution, MMR vaccine must be stored at 2°C to 8°C (35.6°F–46.4°F) or colder and protected from light to avoid inactivation. After reconstitution, the vaccine should be used within 8 hours or discarded.

Immunogenicity and Efficacy

The vaccine induces an asymptomatic, noncommunicable infection. After vaccination with MMR vaccine, approximately 94% of infants and children develop detectable mumps antibodies with (range, 89–97%).^{85,254,264,396,425,544,548,588,589,647,648} Vaccination induces relatively low levels of antibodies compared with natural infection.^{347,675} After a second dose of MMR vaccine, most people mounted a secondary immune response, approximately 50% had a fourfold increase in antibody titers, and the proportion with low or undetectable titers was significantly reduced from 20% before vaccination with a second dose to 4% at 6 months after vaccination.^{92,306,422}

Although antibody measurements are often used as a surrogate measure of immunity, no serologic tests are available for mumps that consistently and reliably predict immunity. The immune response to mumps vaccination probably involves the humoral and cellular immune response, but no definitive correlates of protection have been identified.

Clinical studies conducted before vaccine licensure involving approximately 7000 children found a single dose of mumps vaccine to be approximately 95% effective in preventing mumps disease.^{348,624,675} However, vaccine effectiveness estimates have been lower in postlicensure studies. The median vaccine effectiveness against mumps has been estimated at 78% for one dose and 88% for two doses.⁴⁷¹ In the United States, estimated vaccine effectiveness for one dose of mumps-containing vaccine is between 81% and 91% in junior high and high school settings^{180,183,341,389,626,684} and between 64% and 76% among household or close contacts.^{452,626} Population and school-based studies conducted in Europe and Canada report comparable estimates of 49% to 92% for vaccine effectiveness.^{104,181,202,233,241,335,431,555,584,612,641}

Fewer studies have been conducted to assess the effectiveness of two doses of mumps-containing vaccine. In the United States, outbreaks

among populations with high two-dose coverage found two doses of mumps-containing vaccine to be 80% to 92% effective in preventing clinical disease.^{452,581} In the 1988 through 1989 outbreak among junior high school students, the risk of mumps was five times higher for students who received one dose compared with students who received two doses.³⁴¹ Population and school-based studies in Europe and Canada estimate two doses of mumps-containing vaccine to be 66% to 95% effective.^{104,202,233,241,335,578,612} Despite relatively high two-dose vaccine effectiveness, high two-dose vaccine coverage may not be sufficient to prevent all outbreaks.^{5,216,229}

Studies indicate that one dose of MMR vaccine can provide persistent antibodies to mumps. Most people (70–99%) examined approximately 10 years after initial vaccination had detectable mumps antibodies.^{92,306,422} T-lymphocyte immunity to mumps was found in 70% of adults vaccinated in childhood compared with 80% of adults who acquired a natural infection during childhood.^{213,332} In two-dose recipients, mumps antibodies were detectable in 74% to 95% of people followed over 12 years after receipt of a second dose of MMR vaccine, but antibody levels declined with time.^{227,422} Mumps antigen-specific lymphoproliferative responses have been detected in vaccine recipients without detectable mumps antibodies, but the role of these responses in protection against mumps disease is not clear.^{377,653}

Adverse Events

The use of mumps vaccine is associated with very few side effects. Parotitis and fever have been reported rarely. Hypersensitivity reactions, including rash, pruritus, and purpura, have been associated temporally with vaccination, but they are transient and usually mild. Administration of MMR is not harmful if it is given to an individual already immune to one or more of the viruses.^{40,471}

The frequency of reported central nervous system dysfunction after vaccination is not greater than the observed background rate for unimmunized people.⁴⁷¹ The IOM concluded that evidence is inadequate to establish a causal relationship between the Jeryl Lynn strain of mumps vaccine used in the United States and aseptic meningitis, encephalitis, or sensorineural deafness.³⁶²

Indications

Routine active immunization as MMR of children 12 to 15 months of age is recommended.^{40,471} Most children receive a second dose of mumps vaccine in childhood as a result of the recommendation for routine measles revaccination with MMR. Susceptible older children, adolescents, and adults also should be vaccinated against mumps.

Evidence of immunity through documentation of vaccination is defined as one dose of live mumps vaccine for preschool-aged children and adults not at high risk for exposure and infection and two doses of live mumps vaccine for school-aged children (i.e., kindergarten to grade 12) and adults at high risk for exposure and development of infection (i.e., health care workers, international travelers, and students at post-high school education institutions). Additional recommendations for outbreak control include administering a second dose of MMR for preschool-aged children and adults not at high risk for exposure and acquisition of infection if these people are part of a group that is experiencing an outbreak.¹⁵⁰

To ensure high levels of immunity, especially among groups at high risk for exposure and development of infection, every opportunity should be used to provide the first or second dose of MMR vaccine to those without adequate evidence of immunity (e.g., documentation of vaccination). No formal recommendation for a third MMR dose exists, but the CDC has provided guidelines for public health agencies considering its use as a control measure during mumps outbreaks.²⁶⁶ Factors that can trigger a recommendation include outbreaks in populations with two-dose MMR vaccination coverage of greater than 90%, intense exposure settings such as universities, evidence of sustained transmission for greater than 2 weeks, and high attack rates (>5 cases/1000 people).

Mumps remains endemic throughout most of the world. Although vaccination against mumps is not a requirement for entry into any country, susceptible children, adolescents, and adults born after 1956 should be offered mumps vaccination, usually as MMR, before engaging in international travel.

Mumps vaccine has no proven value in the prevention of disease in susceptible individuals after exposure to mumps, probably because the time required to develop protective antibody titers after immunization exceeds the incubation period of clinical mumps. However, if the exposure does not result in infection, the vaccine confers subsequent immunity.

Precautions and Contraindications

For people who are allergic to eggs, the risk of serious allergic reactions such as anaphylaxis after receiving MMR is extremely low, and skin testing with vaccine cannot predict an allergic reaction to vaccination.^{40,369,386} Performing skin testing is not required before administering MMR to people who are allergic to eggs. Similarly, the administration of gradually increasing doses of vaccine is not required.⁴⁷¹ Data indicate that most anaphylactic reactions to measles- and mumps-containing vaccines are not associated with hypersensitivity to egg antigens but rather with hypersensitivity to other components of the vaccines, such as the gelatin stabilizer.^{311,340,385,419}

Because of the theoretical risk of fetal damage, mumps vaccine should not be administered to women known to be pregnant or who are considering becoming pregnant. Women vaccinated with MMR should avoid conception for 28 days after vaccination.⁴⁷¹

Lymphoreticular or other generalized malignancy and primary or secondary immunodeficiency states represent contraindications to the use of mumps vaccine. Exceptions are children with HIV infection who are immunized against measles with MMR (see [Measles Vaccine](#)). Because infection after vaccination is noncommunicable, susceptible close contacts of immunosuppressed patients should be vaccinated to avoid exposure to mumps in these patients.

After cessation of immunosuppressive therapy, mumps vaccine usually is withheld for at least 3 months. Because the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors determine when immunologic responsiveness will be restored, making a definitive recommendation for an interval after cessation of immunosuppressive therapy when mumps vaccine can be safely and effectively administered often is not possible.

The effect of immune globulin preparations on the response to mumps vaccine is unknown. High doses of immune globulin preparations can inhibit the immune response to measles vaccine for 3 or more months, depending on the dosage.²⁹ If mumps vaccine is given as the MMR vaccine, the recommendations for measles vaccine should be followed (see [Table 245.11](#)).

Administration of mumps vaccine should be avoided if the individual is receiving immunosuppressive dosages of systemic corticosteroids. The effects of corticosteroids vary, but many clinicians consider that a dose equivalent to 2 mg/kg per day or 20 mg/day of prednisone is sufficiently immunosuppressive to raise concern about the safety of vaccination with live virus vaccines.

Pertussis Vaccine

Pertussis (i.e., whooping cough), which is caused by the fastidious, gram-negative, pleomorphic bacillus *B. pertussis*, continues to produce significant morbidity and mortality worldwide among young children.⁴⁹¹ In the absence of vaccination, the WHO estimated that approximately 1 million deaths would have occurred from the disease and its complications. In the United States, the number of cases has been reduced by approximately 95% during the vaccine era.

Despite an effective vaccine, pertussis continues to occur in the United States in all age groups. Since the historic low point achieved in the 1980s, the incidence of pertussis has increased steadily. Outbreaks have occurred recently in California, Washington, and Minnesota. In the California outbreak, there was a degree of clustering within populations for whom vaccination rates, largely due to nonmedical exemptions, were low.⁶⁰ Nonmedical exemption laws appear to increase the rates of pertussis in local areas of undervaccination in the unvaccinated and vaccinated population.^{60,706}

Surveillance data collected by the CDC's National Immunization Program for the periods from 1994 through 1996 and 1997 through 2000 demonstrated that the incidence of pertussis increased 60% among adolescents and adults and 11% among infants younger than 6 months.¹⁴²

Data from the National Notifiable Disease Surveillance System reveal an escalation in the increase in all age groups between 2001 and 2004.⁹⁰ Incidence rates for the pediatric population peak for infants younger than 6 months and again during adolescence between 11 and 18 years of age.²¹ The increase in the number of cases among young infants suggests that a true increase in pertussis circulation has occurred. The number of cases among children old enough to receive vaccine has remained stable. The likely reason that pertussis remains endemic in the United States despite high vaccination rates is that neither infection nor immunization provides life-long immunity.

Humans are the only known reservoir for pertussis. Vaccine effectiveness falls off rapidly after immunization, with rates of 68% after the first year dropping to 8.9% after 4 years.³⁹³ Pregnant woman who have received Tdap in the third trimester of pregnancy had significant declines in immunity 9 to 15 months after delivery.¹

The experiences of countries where rates of pertussis vaccination have markedly declined provide strong support for continuing routine immunization of infants and young children.¹⁸⁸ In the United Kingdom, as a result of adverse publicity about pertussis vaccination, a decrease in immunization rates for 2-year-old children from 77% in 1974 to 30% in 1978 was followed by an epidemic of 102,500 cases of pertussis. A similar experience occurred in Japan, which reported 13,105 cases and 41 deaths in 1979 after routine immunization had been suspended temporarily in 1975.

In the United States during the 1980s, publicity about alleged serious reactions to pertussis vaccine generated public controversy about the risk of receiving pertussis vaccine. This resulted in costly litigation and escalating vaccine costs and jeopardized vaccine supply and development.^{490,532} The experience in countries such as England and Japan, the severity of pertussis in young infants, and the usually benign or self-limited sequelae of pertussis vaccination clearly justify continuing routine childhood immunization. Several risk-benefit analyses provided additional evidence in support of vaccination.^{188,349}

Effective primary preventive programs necessitate immunizing young infants, usually beginning at 2 months of age, because the morbidity and mortality of pertussis are greatest for infants, especially those younger than 6 months.^{123,188} Approximately 26% of reported cases in the United States occur in infants younger than 6 months. During the period from 1997 through 2000, the case-fatality rate for infants younger than 6 months was 0.8%; 63% of these infants were hospitalized with frequent complications, including pneumonia (11.8%), seizures (1.4%), and encephalopathy (0.2%).¹⁴² From 2000 through 2004, 100 pertussis-related deaths were reported; 90% were among infants younger than 4 months, and 76% occurred in infants younger than 2 months.⁹⁰

In 2014, 23,971 cases of pertussis were reported to the CDC; 9935 cases occurred during an outbreak in California to produce a rate of 26 cases per 100,000 people, with a rate of 1746 cases per 100,000 infants younger than 12 months. Three deaths were attributed to this outbreak, all were infants with an onset of illness at less than 5 weeks of age.⁶⁹¹

Maintaining high rates of immunization in children beyond infancy, with booster immunization for adolescents and adults, may reduce the risk of infection in infants by decreasing the incidence of infection in older family members and the resultant transmission of *B. pertussis* within the household. Vaccination, including boosters, is essential because the disease is highly infectious, and transmission often occurs before adults seek medical care.

Preparations

Whole-cell pertussis vaccine was introduced in the United States in the 1920s. Not until the 1940s to 1950s, however, did pediatric whole-cell pertussis vaccine become routinely recommended for children. This vaccine, unavailable in the United States since 2002, consisted of a suspension of inactivated *B. pertussis* combined with diphtheria and tetanus toxoids (DTP).⁹⁰

To reduce the incidence of local and systemic reactions caused by whole-cell vaccines, less reactogenic pediatric acellular vaccines composed of one or more purified components of *B. pertussis* combined with diphtheria and tetanus toxoids (DTaP) were developed. Initially licensed in 1991 for use as the fourth or fifth dose in the series, DTaP was licensed in 1997 for all five doses in the series.

TABLE 245.16 Acellular Pertussis Vaccines Licensed for Use in the United States

Vaccine	Trade Name	Vaccine Manufacturer	No. of Pertussis Antigens	Antigenic Content	Dose Series Approved
DTaP Vaccines for Children Age <7 Years					
DTaP	Daptacel	Sanofi Pasteur	5	PT, FHA, PE, 2 types of FIM	All 5 doses
DTaP	Infanrix	GlaxoSmithKline Biologicals	3	PT, FHA, PE	All 5 doses
DTaP-IPV	Kinrix	GlaxoSmithKline Biologicals	3	PT, FHA, PE	Booster dose for 5th dose of DTaP and 4th dose of IPV, children 4 through 6 years of age
DTaP-hepatitis B-IPV	Pediarix	GlaxoSmithKline Biologicals	3	PT, FHA, PE	First 3 doses, children 6 wk–6 y of age
DTaP-IPV/Hib	Pentacel	Sanofi Pasteur	5	PT, FHA, PE, 2 types of FIM	First 4 doses, children 6 wk–4 y of age
DTaP-IPV	Quadracel	Sanofi Pasteur	5	PT, FHA, PE, 2 types of FIM	Booster dose for 5th dose of DTaP and 4th dose of IPV, children 4–6 y of age
Tdap Vaccines for Adolescents					
Tdap	Adacel	Sanofi Pasteur	5	PT, FHA, PE, 2 types of FIM	Single dose at 11–12 y of age instead of Td
Tdap	Boostrix	GlaxoSmithKline Biologicals	3	PT, FHA, PE	Single dose at 11–12 y of age instead of Td

DTaP, Diphtheria–tetanus–acellular pertussis; FHA, filamentous hemagglutinin; FIM, fimbriae; Hib, *Haemophilus influenzae* type b vaccine; IPV, inactivated poliovirus vaccine; PE, pertactin; PT, pertussis toxin; Td, tetanus and reduced diphtheria toxoids; Tdap, tetanus–diphtheria–acellular pertussis.

Modified from American Academy of Pediatrics. Pertussis (whooping cough). In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:608–21.

Numerous acellular vaccines formulated from the different components have been tested in children. All currently US licensed vaccines contain detoxified or inactivated pertussis toxin (i.e., pertussis toxoid) and filamentous hemagglutinin.²³¹ Most vaccines include one or both of the following *B. pertussis* antigens: pertactin (PRN, a 69-kd outer membrane protein) and fimbriae proteins (FIM, agglutinogens). Various vaccines have different amounts of each component. No pertussis-only vaccine is available.

From 2001 until 2008, numerous changes were made to the list of licensed acellular pertussis–containing vaccines available in the United States. Several acellular vaccines are available for use in the primary vaccination series for children younger than 7 years (Table 245.16).

For enhanced control of pertussis, routine revaccination of adolescents and adults with an acellular pertussis vaccine is recommended to minimize the morbidity associated with infection in these age groups and to reduce the reservoir of infection. Tdap vaccines contain the same pertussis antigen components as are in the pediatric vaccines (some in reduced quantities). The tetanus and diphtheria components are the same as for the current adult formulations of Td, with reduced diphtheria content as recommended for use in people 7 years of age or older.

The ACIP recommends that whenever feasible, the same DTaP vaccine product should be used for all doses of the vaccination series. If the vaccine provider does not know or does not have available the type of DTaP previously administered, any of the available licensed DTaP vaccines can be used to complete the vaccination series.¹³⁸

Immunogenicity

The Multicenter Acellular Pertussis Trial evaluated the immunogenicity and safety of 13 acellular pertussis–containing vaccines compared with whole-cell DTP administered to infants at 2, 4, and 6 months of age in the United States.²³¹ Serologic correlates of immunity to diphtheria and tetanus toxoids, defined as antibody levels 0.1 IU/mL or greater, were achieved after vaccination with acellular vaccines and were comparable with those achieved with DTP vaccination. Pertussis immunity, determined by at least a fourfold rise in antibody titer to pertussis toxin and filamentous hemagglutinin, was equal to or greater than results with DTP after immunization with either of the two DTaP vaccines.²⁵³

Efficacy

For whole-cell and acellular vaccines, serologic correlates of immunogenicity have not been established for assessing efficacy. Field and other

epidemiologic studies must be performed to demonstrate efficacy. Studies in the United States of household contacts exposed to pertussis indicate that the efficacy of whole-cell vaccine was 80% or greater.^{123,188,513} Studies reporting lower rates of vaccine efficacy often reflect the use of different criteria for the diagnosis of pertussis and lesser effectiveness of the vaccine in protecting against mild infection than against severe disease.²⁶⁸ Vaccine-induced immunity persists for at least 3 years and subsequently diminishes with time.

Pertussis in individuals previously vaccinated is less severe and is associated with fewer complications than in unvaccinated people. In a case-control study of pertussis, immunization of both parents decreased the incidence of disease by 51% among infants younger than 4 months.⁶⁹¹ Vaccine effectiveness in pregnant women is 91%.⁵⁰

In studies of the efficacy of eight acellular pertussis vaccines in infants, rates of prevention of pertussis ranged from 58% to 93%.⁵⁴¹ Comparing efficacy of the different products, however, often is not possible because of differences in study design, vaccine schedule (i.e., number of doses and age of administration), case definitions of pertussis, and other confounding variables. The acellular vaccines appear to be similar in efficacy to most whole-cell vaccines. Whereas in two large trials in Sweden and Italy, several acellular vaccines demonstrated substantially greater efficacy than seen in the one US whole-cell vaccine previously approved, other whole-cell vaccines studied appeared to be slightly more effective than acellular vaccines in other trials.²⁵² The vaccines in the Swedish and Italian trials were given in a three-dose schedule, in contrast to the four-dose primary schedule for vaccination of young children in the United States.

Adverse Events

Local and febrile reactions to whole-cell vaccines occur in more than one half of DTP recipients.²⁰⁰ These manifestations usually develop within the first 24 hours and are brief in duration. More serious reactions to whole-cell vaccines are uncommon. The reactions include prolonged crying for 3 hours or longer occurring within the first 48 hours of receiving vaccination (1% to 3% of DTP recipients) and a temperature of 40.5°C or greater (≥104.9°F) within 48 hours (0.3%); a hypotonic-hyporesponsive episode described as collapse or shock-like state within 48 hours and seizure within 3 days of vaccination was estimated to occur once per 1750 doses.²⁰⁰ Episodes of inconsolable crying, high fever, and hypotonic-hyporesponsive episodes after receipt of DTP vaccine resolved without sequelae.

Most post-DTP seizures occurring within 48 hours of receipt of vaccine are brief, self-limited, and generalized and occur in association

with fever. These seizures have not been demonstrated to result in the subsequent development of epilepsy or other neurologic sequelae. Predisposing factors include an underlying convulsive disorder, a personal history of previous convulsion, and a family history of convulsions.¹²⁸ A small increase in the risk of febrile seizure but no increased risk in the development of epilepsy after immunization has been reported.⁶²⁷

The incidence of local and febrile reactions after the administration of acellular vaccines is significantly lower.^{231,541} Comparison of rates of adverse events with different acellular vaccines versus whole-cell vaccines demonstrated similar safety profiles for each of the vaccines.^{193,585} The most common adverse events include injection site reactions (e.g., erythema, induration, tenderness) and mild system symptoms, including slight to moderate fever, drowsiness, irritability, and loss of appetite.

Rates of local reactions increase with each subsequent dose of DTaP vaccine.^{537,642} Booster doses of acellular pertussis vaccine may be associated with extensive local swelling (i.e., limb swelling), especially with vaccines having a high diphtheria content.⁵⁵⁴ The pathogenesis of this reaction is not understood, but it spontaneously resolves without sequelae and is not associated with an increased risk of similar adverse events occurring after receipt of the fifth dose.⁴¹ Severe reactions to acellular vaccines such as prolonged crying of 3 hours or more, temperature greater than or equal to 40.5°C (104.9°F), hypotonic-hyporesponsive episodes, and seizures are rare.^{193,231,309,323,541,585,644} As with local and febrile reactions, their occurrence with acellular pertussis vaccination is significantly less frequent than that after whole-cell vaccination.

Syncope can occur after immunization with Tdap, is more common among adolescents and young adults, and can result in serious injury if a vaccine recipient falls. Vaccinees should be seated and observed for 15 minutes after immunization. If syncope occurs, patients should be observed until symptoms resolve.⁴¹

When administered in the third trimester of pregnancy as recommended by the ACIP, there has been no association with an increased risk of maternal or neonatal death, preeclampsia, hemorrhage, uterine rupture, caesarean section, renal failure, premature delivery, decreased birth weight, or prolonged stay in a neonatal intensive care unit with administration of Tdap. Increases in poor birth outcomes or maternal adverse events have not been observed among women receiving multiple Tdap vaccines during pregnancies spaced less than 5 years apart.^{243,488,625} This finding was confirmed in a review of reported adverse events following the recommendation that pregnant women received Tdap during the third trimester of each pregnancy regardless of prior vaccine history.⁴⁸⁹

Serious Neurologic Illness

The National Childhood Encephalopathy Study (NCES), a large case-control study from Great Britain that was published in 1985, estimated that the occurrence of acute neurologic illness resulting in hospitalization was 1 case per 140,000 DTP vaccinations.⁴⁸¹ In a 10-year follow-up study published in 1993, neurologic sequelae were found to be common occurrences, but no more so than in children with unrelated, acute neurologic illness in infancy,⁴⁸⁰ and reviews of the data have disputed the conclusion that pertussis vaccine can cause neurologic sequelae.^{14,128,622} Later data from Canada evaluating more than 12,000 pediatric hospitalizations for serious neurologic illness between 1993 and 2002 found no association after administration of more than 6.5 million doses between development of encephalopathy and receipt of DTaP vaccination.⁴¹ Taken together, the data do not support a role for whole-cell pertussis vaccine in causing brain damage.¹¹⁵

Indications

Vaccination against pertussis with DTaP is recommended routinely for children at 2, 4, and 6 months of age, followed by a fourth dose at 12 to 18 months of age and a fifth dose at 4 to 6 years of age.^{21,41,90} Immunization can be started when the child is as young as 6 weeks of age if pertussis is prevalent in the community. The interval between administrations of the three doses of the initial series can be as short as 4 weeks. The AAP and ACIP recommend exclusive use of acellular pertussis vaccines for all doses of the pertussis vaccine series.^{21,41,90} DTP is no longer available in the United States. However, in many countries, including several in Europe and developing countries, whole-cell vaccine remains the recommended product.

A single dose of Tdap is recommended universally for people 11 years or older, including adults, in place of the initial Td booster vaccine. The preferred schedule is to administer Tdap at the preventive visit for the 11- or 12- year-old children who have completed their primary DTP/DTaP series.^{21,41,90} Adolescents and adults 11 years or older who received Td but not Tdap should receive a single dose of Tdap to provide protection against pertussis. Tdap can be administered regardless of the time since receipt of the last tetanus- or diphtheria-containing vaccine.⁴¹ Adolescents between the ages of 11 and 18 years who have never been vaccinated against tetanus, diphtheria, or pertussis should initially receive a single dose of Tdap followed by Td for the subsequent two doses at 4 weeks or more and 6 to 12 months later.

No pertussis-containing vaccine is FDA approved for children between the ages of 7 and 10 years. If pertussis vaccine is not contraindicated, children 7 through 10 years of age who are not fully vaccinated (i.e., have not received five doses of DTaP or four doses of DTaP if the fourth dose was administered on or after the fourth birthday) should receive a single dose of Tdap to provide protection against pertussis. If additional doses of tetanus and diphtheria toxoid-containing vaccines are needed for children 7 through 10 years of age, Tdap vaccine is substituted as the first dose. The subsequent two doses should be Td vaccine at 4 weeks or more and 6 to 12 months after the previous dose if indicated for the catch-up series.^{29,90}

Women should receive Tdap before becoming pregnant. Women who have not been immunized previously with Tdap should receive Tdap during pregnancy, preferably during the early third trimester (i.e., after 20 weeks' gestation). If it is not administered during pregnancy, Tdap should be administered in the immediate postpartum period.^{171,175} Additional immunization with Tdap should be administered in the early third trimester of each additional pregnancy. Every 10 years thereafter, booster vaccination should be provided by Td.

As further protection against transmission of pertussis to infants who are at greatest risk for pertussis-related morbidity or mortality compared with other age groups, the cocoon strategy is recommended to immunize mothers, families, and close contacts against pertussis to decrease their likelihood of acquisition and subsequent transmission of *B. pertussis* to infants. Adolescents and adults (i.e., parents, siblings, grandparents, child care providers, and health care personnel) who have or anticipate having close contact with an infant younger than 12 months should receive a single dose of Tdap to protect against pertussis if they have not previously received Tdap. Ideally, these people should receive Tdap at least 2 weeks before beginning close contact with the infant.^{41,171}

Contraindications and Precautions

The contraindications and precautions for administering pertussis vaccine are based on adverse reactions associated with whole-cell vaccine. Although reactions occurring after the administration of DTaP are much less common than are those associated with DTP, the contraindications and precautions for DTaP are the same.^{21,41,90} Adverse events temporally related to pertussis immunization that contraindicate further administration of DTaP are as follows:

- An immediate anaphylactic reaction. Subsequent immunization with any of the three components of the vaccine should be avoided.
- Encephalopathy occurring within 7 days. Children who experienced encephalopathy within 7 days after administration of a previous dose of diphtheria and tetanus toxoids and pertussis vaccine (i.e., DTP, DTaP, or Tdap) not attributable to another identifiable cause should not receive additional doses of a vaccine that contains pertussis. Encephalopathy in this context is defined as a severe, acute, central nervous system disorder (e.g., coma, prolonged seizures) unexplained by another cause and may manifest as major alterations in consciousness or generalized or focal seizures that persist for more than a few hours without recovery within 24 hours. Additional doses of DT (or Td) vaccine should be substituted for any pertussis-containing vaccine.

Postvaccination reactions constituting precautions are as follows:

- Moderate or severe acute illness with or without a fever
- Guillain-Barré syndrome within 6 weeks after a previous dose of tetanus toxoid-containing vaccine

- A convulsion, with or without fever, occurring within 3 days of receiving DTP or DTaP vaccination
- Persistent, severe, inconsolable screaming or crying for 3 hours or more within 48 hours of DTP or DTaP vaccination
- Hypotonic-hyporesponsive episode occurring within 48 hours of DTP or DTaP vaccination
- Temperature of 40.5°C (104.9°F) or greater that is unexplained by another cause and occurs within 48 hours of DTP or DTaP vaccination

With these adverse events occurring in temporal association with DTaP vaccination, the decision to administer additional doses of pertussis vaccine should be considered carefully. Children for whom vaccination is deferred because of moderate or severe acute illness should be vaccinated when their condition improves. In circumstances such as a pertussis outbreak in which the potential benefits of pertussis immunization outweigh the possible risks, vaccination is indicated, particularly because these events have not been proved to cause permanent sequelae. The risk of these reactions occurring after receipt of DTaP is substantially lower than after receipt of DTP.

For children with an evolving neurologic disorder in the first year of life, pertussis immunization should be deferred until the nature and cause of the disorder have been established. A personal history of having a stable neurologic condition (i.e., previous convulsion unrelated to DTaP vaccination, a history of seizure disorder, well-controlled seizures, or cerebral palsy) or a family history of convulsions is not a contraindication, and pertussis immunization should be administered on schedule.

Certain conditions after DTaP vaccine, such as temperature of 40.5°C (104.9°F) or higher, collapse or shock-like state, persistent crying, or convulsions with or without fever, are a precaution to subsequent doses of DTaP. However, occurrence of one of these adverse reactions after DTaP vaccine in childhood is not a contraindication or precaution to administration of Tdap to an adolescent or adult. A history of severe Arthus hypersensitivity reaction after a previous dose of a tetanus or diphtheria toxoid-containing vaccine administered less than 10 years earlier should lead to deferral of Tdap or Td immunization for 10 years after administration of the tetanus or diphtheria toxoid-containing vaccine.^{21,41,90}

Pneumococcal Vaccine

S. pneumoniae is a leading bacterial pathogen, especially among young children, elderly people, and people with predisposing conditions. In children, it is the most common cause of otitis media, occult bacteremia, and bacterial pneumonia requiring hospitalization. After the widespread introduction of conjugate Hib vaccination and subsequent marked decline in occurrence of Hib meningitis, *S. pneumoniae* became a leading cause of bacterial meningitis in children in the United States.

In some populations, such as Alaska Natives, the incidence of bacteremia is markedly higher than that reported in other geographic areas of the United States.²²⁸ Groups considered at high risk for invasive pneumococcal disease (IPD) include children with sickle cell disease, asplenia, Hodgkin disease, congenital humoral immunodeficiency, HIV infection, and nephrotic syndrome and recipients of organ transplants. Children who have received cochlear implants are at particular risk for developing meningitis.^{144,552} Other chronic diseases associated with an increased risk of development of severe pneumococcal disease include chronic cardiovascular and pulmonary diseases, diabetes mellitus, and renal failure. The role of these chronic diseases in predisposing individuals to pneumococcal infection has been demonstrated primarily in adults. Mortality rates are highest among those who have bacteremia or meningitis, elderly people, and patients with impaired humoral immunity or certain chronic diseases.

The purified polysaccharide vaccine has been effective in reducing severe disease in the adult population,⁹⁹ but it has little impact in young children because the vaccine is not immunogenic in children younger than 2 years.⁴² The polysaccharide vaccine has not been effective in preventing otitis media caused by *S. pneumoniae*.⁴² Several factors made the development of new preventive strategies for pneumococcal disease a high priority.^{212,214} Morbidity and mortality rates of pneumococcal infection appear to be particularly high in developing countries. The

increasing incidence of antimicrobial-resistant pneumococci further underscores the need for developing effective pneumococcal vaccines for young children.⁸⁸ Resistance of *S. pneumoniae* to multiple antibiotics increased rapidly in the United States and even more rapidly in other parts of the world.³⁸¹ Children younger than 2 years have the highest rate of IPD but do not develop an effective antibody response to polysaccharide vaccine. Children 2 to 5 years of age may have relatively poor responses to serotypes 6B, 14, 19F, and 23F, which are common causes of pediatric infections and the most prevalent penicillin-resistant serotypes.

These factors prompted the development of conjugated polysaccharide–protein vaccines, two of which have been licensed in the United States. These vaccines are similar in design to the licensed Hib conjugate vaccines. Because of the large number of serotypes of *S. pneumoniae* that cause disease, development of these conjugate pneumococcal vaccines was more difficult than the development of similar vaccines for Hib. Each pneumococcal antigen must be coupled to a protein carrier, and the vaccine must be prepared to ensure that antigen is sufficient to induce an immune response but insufficient to elicit an adverse reaction.

One potential problem with conjugate pneumococcal vaccines is the need to immunize against many different serotypes of pneumococci. Because of local reactions to the protein component, conjugate vaccines that contain all implicated serotypes have proved difficult to produce. Initial decisions for serotype inclusion need to be carefully planned for specific groups. For instance, vaccine containing types 4, 6B, 9V, 14, 18C, 19F, and 23F (i.e., PCV7) is necessary for prevention of otitis media in the United States, whereas types 1, 2, and 5 need to be added to prevent pneumonia in developing countries.

The use of conjugate vaccines against limited serotypes has led to emergence of pneumococcal serotypes (e.g., 19A) that were previously less common but have proved equally concerning for IPD and emerging resistance.^{102,161,364} Emergence of replacement serotypes led to the expansion of the previous vaccine to the 13-valent pneumococcal conjugate vaccine (PCV13) in the United States.¹⁶² Routine infant immunization using these conjugate vaccines led to significant reductions in the instances of *S. pneumoniae* disease.²⁶³ Since the widespread introduction of PCV7 in infants in 2000, rates of IPD have decreased markedly in the United States.²⁶³ The incidence of all IPDs has decreased by 80% for children younger than 2 years and by up to 90% for infections caused by vaccine and vaccine-related serotypes.^{42,161,686} An increase in nonvaccine serotype disease has occurred, but it is small compared with the overall reductions in vaccine-type disease.^{52,102,145,161}

A decline in the incidence of vaccine-type disease among unvaccinated children and adults has occurred since the introduction of routine vaccination for infants in the United States.¹⁴⁵ Rates of IPD among infants younger than 2 months have decreased significantly, providing evidence that vaccinating children 2 to 23 months of age has led to changes in pneumococcal carriage in infants who were too young to receive PCV7.⁵⁴³ In surveillance of children with sickle cell disease from 1998 to 2009, rates of IPD fell by 53%.⁵²⁸ As of 2012, PCVs are included in national immunization programs in 86 of 194 WHO member states, with similar expectations of IPD decrease.¹⁷⁴

Herd immunity is estimated to prevent twice as many cases as do the direct effects of vaccination alone.^{145,161} Although the exact mechanism of herd immunity is uncertain, one hypothesis is that vaccinated children are less likely to have nasal carriage of pneumococcus and therefore less pneumococcal transmission to their contacts.²²² Use of conjugate vaccines has reduced nasopharyngeal carriage of vaccine serotypes with PCV7 and PCV13.^{201,223,224} Pneumococcal conjugate vaccination also has led to increased nasopharyngeal colonization of children with nonvaccine serotypes.^{293,479} In surveillance of IPD cases among children younger than 5 years, the introduction of PCV7 decreased penicillin-nonsusceptible cases by 64%, with serotypes not in PCV7 causing 78% to 97% of penicillin-nonsusceptible IPD.³³¹ This underscores the need for ongoing surveillance of emerging nonvaccine serotypes with respect to nasopharyngeal colonization, antibiotic nonsusceptibility and of rates of IPD.⁶¹³

Preparations

Two pneumococcal vaccines are available for use in children in the United States. The first is a 13-valent vaccine (PCV13) licensed in 2010

(Prevnar, Wyeth Vaccines), which contains the capsular polysaccharides from serotypes contained in the previous PCV7 (i.e., 4, 6B, 9V, 14, 18C, 19F, and 23F) and six additional serotypes (i.e., 1, 3, 5, 6A, 7F, and 19A) conjugated to mutant diphtheria toxin (CRM197).⁴² Serotypes included in PCV7 and potentially cross-reactive serotypes (i.e., 6A, 9A, 9L, 18B, and 18F) accounted for 86% of cases of bacteremia, 83% of cases of meningitis, and 65% of AOM cases occurring in children younger than 6 years in the United States during 1978 to 1994.⁵⁰⁹ In 2007, the Active Bacterial Core surveillance estimated 4600 cases of IPD among children younger than 5 years in the United States, with 2900 attributable to serotypes covered by PCV13 versus 60 cases covered by PCV7.¹⁶¹ The incidence of IPD from PCV13 or nonPCV7 serotypes was reduced by 64% and 93%, respectively, among children younger than 5 years by 2013, driven mostly by reductions of serotypes 19A and 7F.⁴⁸⁷

The second vaccine (i.e., PPV23 [Pneumovax]) is composed of purified, capsular polysaccharide antigens of 23 pneumococcal serotypes. Although 90 different serotypes have been identified, vaccine serotypes in the 23-valent vaccine are historically responsible for 85% to 90% of adult infections and almost 100% of invasive disease and 85% of otitis media cases in children.^{112,294} Each vaccine is recommended in a dose of 0.5 mL that is given intramuscularly.

Immunogenicity and Efficacy

The immunogenicity of the conjugate polysaccharide vaccine appears to be determined by the pneumococcal polysaccharide serotype, rather than by the carrier protein. Some serotypes (i.e., 14, 18C, and 19F) are excellent immunogens because they elicit antibody protection after a single dose, whereas others (i.e., 6B and 23F) require three doses of vaccine.²⁵⁹ Conjugate vaccine elicits immunologic memory.²⁵⁹ The antibody concentrations achieved after the initial series of three doses usually are sustained for only a few months and then decline to almost preimmunization levels. A dose of pneumococcal vaccine (i.e., polysaccharide or conjugate) given in the second year of life elicits an amnestic-type response.

Preliminary clinical efficacy of PCV7 was studied in a large, prospective, placebo-controlled efficacy trial in northern California involving 38,000 children. The vaccine was 89% effective in preventing invasive disease caused by any pneumococcal serotype and 97% effective against disease caused by the seven vaccine serotypes.⁸⁰ For noninvasive disease, a decrease of 7% in the number of cases of otitis media and 23% in doctor visits for recurrent otitis (i.e., six or more visits per year) occurred for vaccinated children. The study also demonstrated an 11% decrease in the number of clinical cases of pneumonia and efficacy of 26% against a first episode of radiograph-confirmed pneumonia in vaccinees.^{333,600}

Preliminary immunogenicity of PCV13 was studied in a randomized, double-blind, active-controlled trial in which 663 US infants received at least one dose of PCV7 or PCV13. The study was powered for noninferiority of immunoglobulin antibody response measured by enzyme immunoassay and included subset analysis of functional antibody responses measured by opsonophagocytosis assay (OPA).^{25,707} The noninferiority criterion (i.e., immunoglobulin geometric mean concentrations) was met for all shared serotypes; although slightly lower in the PCV13 group, the functional OPA response was similar, suggesting PCV13 has similar efficacy as PCV7 against shared serotypes. After a fourth dose of PCV13, the additional six serotypes also produced a functional OPA response in 97% to 100%.

The ability of PCV7 to protect children against AOM was evaluated in an efficacy trial conducted in Finland.²⁶⁰ For prevention of AOM caused by pneumococci of any serotype, efficacy was estimated to be 34%, whereas efficacy against AOM irrespective of cause was 6%. Efficacy against AOM caused by vaccine-related serotypes was 57%, but an increase of 33% in the rate of AOM episodes caused by nonvaccine serotypes occurred in the group receiving the heptavalent vaccine compared with controls. Despite of the increase in disease caused by nonvaccine serotypes, the net effect on pneumococcal AOM was a reduction of 34%.

RCTs enrolling African children and using a nine-valent pneumococcal conjugate vaccine demonstrated efficacy in the prevention of radiologically confirmed pneumonia and vaccine-type IPD.^{220,398} The vaccine

was efficacious in preventing vaccine-type invasive disease in HIV-infected children.³⁹⁸ One of the trials demonstrated a reduction in the all-cause mortality rate for vaccine recipients.²²⁰ These data make a compelling case for extending the benefits of pneumococcal conjugate vaccination to developing countries.

Vaccination with purified polysaccharide vaccine results in serologic type-specific antibody in most healthy adults and older children. Immunocompromised patients may respond less well. In children younger than 2 years, the antibody response is poor to most serotypes, including those most likely to cause infection, such as types 6A and 14.^{130,112,294} Patients with AIDS have impaired antibody responses to vaccination, but asymptomatic HIV-infected adults do respond.^{130,112}

Vaccine efficacy in preventing serious pneumococcal infection has been demonstrated for the purified polysaccharide vaccine primarily in immunocompetent adults, including elderly people and those with chronic diseases such as chronic pulmonary and cardiac disorders and diabetes mellitus, which predispose these patients to development of pneumococcal infections. Efficacy against vaccine serotypes ranges from 61% to 75% in adults.^{99,594} Investigations in adults in whom vaccine protection against pneumococcal infection has been substantially less have been criticized for methodologic problems.^{130,112} Efficacy in the limited studies of children has been consistent with that for adults. In children with sickle cell disease or anatomic asplenia, an octavalent vaccine was highly effective in preventing bacteremic infection.⁵¹

Adverse Events

Pneumococcal conjugate vaccines appear to be safe, and in 13 clinical trials, the safety profile of PCV13 was comparable to that of PCV7.^{25,42,509} The reactions most commonly reported have been local reactions at the injection site, but they occur at a lower frequency than do local reactions with other childhood vaccines such as DTP.⁸⁰

Local reactions at the injection site, such as erythema and pain, are reported for approximately 50% of recipients of the purified polysaccharide vaccine.⁴² However, more severe local and systemic reactions, such as fever and myalgia, are rare events that occur in less than 1% of vaccine recipients. Severe systemic reactions such as anaphylaxis rarely have been reported.⁶⁹² Preterm infants show safety results comparable with those for term infants.⁴⁶³ In adults who were revaccinated within 1 to 2 years in early studies, local reactions occurred more commonly than did those after initial immunization.^{130,112} However, subsequent investigations, including studies of children, indicated no increase in the incidence or severity of local or systemic reactions on revaccination after longer intervals.^{401,557}

Indications

Recommendations for the use of PCV13 have been issued by the AAP and the ACIP.^{25,509} The AAP and ACIP recommend universal use of PCV13 in children 59 months or younger. For children to whom no prior PCV7 or PCV13 has been administered before they reach 7 months of age, four doses of PCV13 are recommended. Doses should be administered routinely at 2, 4, 6, and 12 to 15 months of age. For children younger than 24 months who have not received their recommended four doses of PCV7, a dose of PCV13 should be administered at the next scheduled vaccination; the total number of doses is based on the child's age and described elsewhere.^{25,42,509}

A single supplemental dose of PCV13 is recommended for all children 14 months to 59 months who have previously received all four doses of PCV7. A single dose of PCV13 is recommended for children 60 months to 18 years of age who are fully immunized with PCV7 and have underlying medical conditions that increase their risk of IPD. For children 6 through 18 years of age, PCV13 should be given regardless of previous PCV7 or PPSV23 administration.⁸⁷ If not previously administered, children 24 months to 18 years of age should receive the PPV23 to expand serotype coverage.

The AAP recommends PPV23 for children 24 months or older and PCV13 for all children 59 months of age or older who belong to one or more of the following risk groups:

- Immunocompetent children with chronic heart disease, chronic lung disease, diabetes mellitus, cerebrospinal fluid leaks, or cochlear implants

- Children with functional or anatomic asplenia, including sickle cell disease or other hemoglobinopathies, congenital or acquired asplenia, or splenic dysfunction
- Children with immunocompromising conditions, including HIV infection; chronic renal failure and nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; or solid organ transplantation and congenital immunodeficiency

For previously vaccinated children 18 years or younger who are at high risk for severe pneumococcal infection, revaccination with PPV23 after 5 years is recommended.^{25,87,509} For children between the ages of 6 and 18 years who have not received PCV13 but have received at least one PPSV23 dose, a single PCV13 dose should be given at least 8 weeks after the last PPSV23 dose, regardless of previously given PCV7.¹⁷⁶ This includes children who have functional (e.g., sickle cell disease) or anatomic asplenia, children and adolescents with HIV infection, and those who have a rapid antibody decline (i.e., nephrotic syndrome, renal failure, or organ transplantation).²⁹⁵ Revaccination with PPV23 should be considered for high-risk older children and adults who were vaccinated 6 years or more earlier, but no more than two total PPV23 doses are necessary. The interval between polysaccharide and conjugate vaccines should be at least 8 weeks, regardless of the order given.³⁹⁹

Contraindications

No contraindications to initial vaccination exist.^{25,509} The safety of pneumococcal vaccine in pregnant women has not been evaluated, but adverse consequences for the fetus have not been observed in neonates whose mothers were vaccinated inadvertently during pregnancy. Ideally, women at high risk for pneumococcal disease should be vaccinated before pregnancy. For people who have had a severe reaction, such as anaphylaxis or a localized, severe hypersensitivity response, revaccination should be avoided.

Poliovirus Vaccine

The widespread implementation of poliovirus vaccine programs resulted in a dramatic reduction in the incidence of paralytic poliomyelitis throughout the world. In contrast to the prevaccine era, when more than 18,000 cases of paralytic disease occurred in the United States annually, the last known case in this country caused by indigenous wild-type virus occurred in 1979.¹⁷⁸ Other than rare imported cases, the only cases of paralytic poliomyelitis in the United States since then have been vaccine related.

The effectiveness of polio vaccination led the WHO to launch the Global Polio Eradication Initiative in 1988, when approximately 350,000 people succumbed to polio each year. The initiative initially made rapid gains; the number of new wild poliovirus cases decreased by 99% between 1988 and 2005. However, ongoing transmission threatened the success of the polio eradication program, and the Polio Eradication and Endgame Strategic Plan 2013–18 was developed under the auspices of the WHO to eradicate wild poliovirus, vaccine-associated paralytic polio (VAPP), and circulating vaccine-derived poliovirus (VDPV).⁷⁰¹ The phased plan was implemented in places where OPV was used routinely. At least one dose of inactivated polio vaccine (IPV) was introduced in 2015, and bivalent OPV (bOPV, types 1 and 3) replaced trivalent OPV (tOPV) starting in 2016. The type 2 component of tOPV is being removed because it causes more than 90% of all cVDPV cases and approximately 40% of vaccine-associated paralytic polio cases, it interferes with the immune response to the other two types, and wild poliovirus type 2 has been eradicated since 1999.

As of 2016, four of the six regions of the WHO have been certified polio-free: the Americas (1994), Western Pacific (2000), Europe (2002), and South East Asia, including India (2014). Eighty percent of the world's population currently lives in polio-free areas. However, Afghanistan, Nigeria, and Pakistan are the three remaining reservoirs of endemic disease, largely because regional conflicts and poor health care infrastructures hinder widespread immunization campaigns. Countries with ongoing outbreaks of cVDPV include Guinea, Lao People's Democratic Republic, Madagascar, Myanmar, Nigeria, and Ukraine.^{516,539,701}

The elimination of poliovirus infection has been achieved primarily through the use of OPV (i.e., Sabin strain). This product had been the vaccine of choice for children in the United States since the early 1960s because it induced optimal intestinal immunity, was painless to administer, and secondarily immunized some contacts by fecal-oral spread of the vaccine virus and contributed to the immunity of the population.¹⁰⁵ Because 8 to 10 cases of vaccine-associated paralytic polio occurred annually and the risk of exposure to wild poliovirus had been markedly reduced or eliminated in the United States, expanded use of IPV (i.e., Salk strain) was recommended by the CDC and the AAP beginning in 1997.^{16,129}

In 1999, as a result of progress in the global eradication of poliomyelitis, the need for further reduction in the risk of acquiring vaccine-associated paralytic polio, and the acceptance of IPV by parents and physicians,¹³¹ IPV was recommended for the first two doses of poliovirus vaccine for routine childhood vaccination.^{18,134} To eliminate the risk of vaccine-associated paralytic polio completely, an all-IPV schedule was recommended in January of 2000 for routine childhood vaccination in the United States.^{19,137,134} IPV is the only vaccine used in developed countries.

Since 2000, there have been ongoing outbreaks of paralytic poliomyelitis caused by circulating VDPVs that are neurovirulent polioviruses derived from the Sabin OPV vaccine strain. The epidemics have occurred among underimmunized children living in certain economically deprived regions. The low immunization rates in these areas have permitted these viruses to circulate for long periods and, by continuous mutation, to acquire biologic properties that are indistinguishable from naturally occurring wild polioviruses. Interruptions in OPV administration and the previous eradication of the corresponding serotype of indigenous wild poliovirus were the critical risk factors for all VDPV outbreaks.³⁸⁷ Circulation of VDPVs underscores the critical importance of eliminating the last pockets of wild poliovirus, maintaining universally high levels of polio vaccine coverage (>90% of young children), withdrawing all OPVs as soon as wild poliovirus has been eradicated globally, and continuing poliovirus surveillance into the foreseeable future.

Preparations

Trivalent IPV is the only vaccine available for routine infant and childhood immunization in the United States. IPV is prepared by inactivation of naturally occurring polioviruses by treatment with formaldehyde. Five trivalent IPV vaccines are available in the United States: IPOL (single-component vaccine [Sanofi Pasteur]), Pediarix (in combination with DTaP vaccine and HBV vaccine [GlaxoSmithKline]), Pentacel (in combination with DTaP and Hib vaccines [Sanofi Pasteur]), Quadracel (in combination with DTaP vaccine [Sanofi Pasteur]), and Kinrix (in combination with DTaP vaccine [GlaxoSmithKline]). These vaccines are produced in monkey kidney (Vero) cells except for Pentacel, which is grown in human diploid cells, and each contains 40, 8, and 32 D-antigen units of poliovirus types 1, 2, and 3, respectively. The single-component vaccine is the only IPV preparation that contains preservative.

The trivalent OPV formulations contain approximately $10^{6.5}$ 50% tissue culture infectious doses (TCID₅₀), $10^{5.5}$ TCID₅₀, and $10^{6.2}$ TCID₅₀ of poliovirus types 1, 2, and 3, respectively, in a 10:1:3 ratio. The unequal contribution of each type to the trivalent preparation represents a balanced formulation designed to account for the more efficient replication of type 2 OPV virus in the gastrointestinal tract and to avoid interference with the replication of the two latter types. The live oral OPV strains are grown in Vero cells and do not contain a preservative. OPV is no longer available in the United States.

Monovalent OPV (mOPV) vaccines (types 1 and 3) are recommended for use in supplementary immunization campaigns where only wild poliovirus type 1 or type 3 alone is circulating, with the purpose of controlling outbreaks. Two doses of mOPV administered within 2 weeks is used as part of the short-interval additional dose approach, which is intended to rapidly boost population immunity in certain settings.⁶⁷⁰

Immunogenicity and Efficacy

Neutralizing antibodies are detectable to all three poliovirus types in 99% of recipients of IPV after two doses and in 100% after the third

dose.^{468,606} Detectable antibody persists at protective levels for at least 5 years, although geometric mean titers decline considerably.⁶³⁰ A meta-analysis revealed that vaccine efficacy of the currently licensed enhanced-potency IPV formulations ranges from 33% to 47% after one dose and 79% to 90% after two doses in infants older than 10 weeks.³⁰⁸

An optimal immune response to trivalent OPV requires multiple doses. In developed countries, three doses given at least 2 months apart are sufficient, with antibody prevalence to all three types being approximately 96% after the third dose.⁴⁶⁸ Detectable serum antibody to all three types persists in 84% to 98% of vaccinees 5 years after receiving primary immunization.⁴¹¹

OPV efficacy was directly evaluated during a type 1 poliovirus outbreak in Taiwan in the early 1980s. During this outbreak, vaccine efficacy was estimated to be 82%, 96%, and 98% for one, two, and three or more doses, respectively.³⁹⁰ In tropical countries, the series of OPV at 6, 10, and 14 weeks of age recommended by the WHO EPI fails to produce active immunity in a significant proportion of infants. Low seroconversion rates have been documented in many locations, averaging 73%, 90%, and 70% for types 1, 2, and 3, respectively.⁵²⁶ Diarrheal disease at the time of immunization is a major factor.⁴⁹⁶ The impact of diarrhea on seroconversion persists despite the administration of three or four OPV doses.

The monovalent OPV vaccines have higher type-specific seroconversion rates than does the trivalent vaccine and are considered more effective when used in response to an outbreak caused by one poliovirus type.¹⁰³

Adverse Events

No serious adverse events have been associated with use of the currently available IPV vaccine.^{19,43,134} Because IPV vaccine contains trace amounts of streptomycin, neomycin, and polymyxin B, allergic reactions are possible in recipients with hypersensitivity to one or more of these antibiotics.

The OPV vaccine can cause vaccine-associated paralytic polio, the overall risk for which is approximately one case per 2.4 million doses distributed. The rate after the first dose is approximately one case per 750,000 doses, including vaccine recipient and contact cases. Immunodeficiency-related VDPV excretion by people with primary immunodeficiencies is a rare complication of OPV use and is associated with chronic excretion and fatal disease.⁹⁸

Indications

The polio vaccination series in the United States consists of four doses of IPV administered subcutaneously or intramuscularly.^{19,43,134} The first and second doses are administered at 2 and 4 months of age, respectively. The third dose is usually given at 6 to 18 months of age, and a fourth dose is given routinely at 4 to 6 years of age, before school entry. Administration of a fourth dose is not necessary if the third dose was given on or after the child's fourth birthday. IPV is a component of Pediarix, Pentacel, Quadracel, and Kinrix. Pediarix may be given from 6 weeks through 6 years of age. Pentacel may be used 6 weeks through 4 years of age, and Quadracel and Kinrix may be used for children 4 to 6 years of age.

The WHO continues to recommend OPV as the vaccine of choice for global eradication of wild poliovirus in endemic areas and during epidemics. Since 2015, at least one additional dose of IPV is recommended from 14 weeks of age, with or without a concurrent OPV dose, in preparation for withdrawing all OPV after global eradication has been certified. Since 2016, trivalent OPV has been switched to bivalent OPV (i.e., types 1 and 3). In the immunization schedule of the WHO EPI, doses of OPV are recommended at birth and when the child is 6, 10, and 14 weeks of age.²⁹ In geographic areas with endemic polio, a dose may be given when the neonate is discharged from the hospital (i.e., the zero dose). Supplementary doses often are given during mass community programs in these areas. Breastfeeding does not interfere with successful immunization with OPV.

Routine poliovirus vaccination is not necessary in adults residing in the United States. These individuals are at minimal risk for exposure, and most are adequately protected because of vaccination during

childhood. However, vaccination is recommended for individuals who have an increased risk of exposure, including people traveling to countries where poliomyelitis is epidemic or endemic, members of communities of specific population groups experiencing wild poliovirus disease, health care workers in close contact with patients who may be excreting wild poliovirus, and laboratory workers in contact with specimens that may contain wild-type poliovirus. Previously immunized adults who are at increased risk for exposure to poliomyelitis, such as those traveling to countries where poliomyelitis is still endemic, should receive a single dose of IPV. Available data do not indicate the need for more than a single lifetime booster dose of IPV. Adults who are unvaccinated or whose vaccination status is not documented should receive a primary vaccination series with IPV. This consists of two doses of IPV at 4- to 8-week intervals and a third dose 6 to 12 months after the second dose.

Precautions and Contraindications

IPV is contraindicated in people who have had an anaphylactic reaction after receiving a previous dose of IPV or an anaphylactic reaction to one of the antibiotics in the vaccine preparation (i.e., streptomycin, polymyxin B, or neomycin).^{19,43,134} Poliomyelitis vaccination usually is contraindicated in pregnant women because of the theoretical risk of harm to the fetus. However, no deleterious effects from IPV administered during pregnancy have been demonstrated; and if immediate protection against poliomyelitis is needed, IPV may be given.

Rotavirus Vaccine

Rotavirus infection is the most common cause of severe diarrhea disease in infants and young children worldwide and continues to have a major global impact on childhood morbidity and mortality, causing an estimated 527,000 deaths of children younger than 5 years each year or approximately 5% of all childhood deaths worldwide.⁵²¹ In the United States before the introduction of vaccine in 2006, an estimated 3 million rotavirus infections occurred every year, and 95% of children had at least one rotavirus infection by 5 years of age. Rotavirus infection was responsible for more than 400,000 physician visits, more than 200,000 emergency department (ED) visits, 55,000 to 70,000 hospitalizations, and 20 to 60 deaths each year of children younger than 5 years.^{298,688} In the prevaccine era, rotavirus accounted for 30% to 50% of all hospitalizations for gastroenteritis among US children younger than 5 years.²¹⁷

Rotavirus gastroenteritis is preventable with live oral rotavirus vaccines. In 1998, the only approved rotavirus vaccine, a tetravalent rhesus-based rotavirus vaccine (RRV-TV) (Rotashield, Wyeth Laboratories), was withdrawn from the market in the United States because of an association with intussusception among vaccinated infants.⁴⁹⁵ In 2006, a bovine-based pentavalent rotavirus vaccine (RotaTaq, Merck & Co.) was licensed by the FDA for use in infants in the United States. The ACIP of the CDC and the AAP have recommended universal vaccination of US infants against rotavirus.^{24,217} In 2008, a live attenuated human rotavirus vaccine (Rotarix, GlaxoSmithKline) was licensed in the United States.

The epidemiology of rotavirus disease in the United States has changed dramatically since rotavirus vaccines became available in 2006. National declines in rotavirus detection have been reported, ranging from 58% to 90% in each of the seven postvaccine years compared with all seven prevaccine years combined. A biennial pattern of rotavirus activity emerged in the postvaccine era, with years of low activity and highly erratic seasonality alternating with years of moderately increased activity and seasonality similar to that seen in the prevaccine era.⁹ Other US studies show the large public health impact of routine rotavirus vaccination in reducing the circulation of rotavirus among US children. Declines in laboratory-confirmed rotavirus hospitalization⁶³² and reductions in outpatient visits, emergency room visits, acute gastroenteritis, and rotavirus-coded hospitalizations have been reported.²¹⁵ From 2007 through 2011, more than 176,000 hospitalizations, 242,000 emergency department visits, and 1.1 million outpatient visits due to diarrhea were averted, resulting in costs savings of \$924 million over the 4-year period.⁴²⁷

Preparations

Two rotavirus vaccines are licensed for use in the United States. The pentavalent rotavirus vaccine (RV5) is an oral vaccine that contains

five live reassortant rotaviruses. The rotavirus parent strains of the reassortants were isolated from human and bovine hosts. Four reassortant rotaviruses express one of the outer capsid proteins (i.e., G1, G2, G3, or G4) from the human rotavirus parent strain and the attachment protein (i.e., P7[5]) from the bovine rotavirus parent strain. The fifth reassortant virus expresses the attachment protein (i.e., P1A[8]) from the human rotavirus parent strain and the outer capsid protein (i.e., G6) from the bovine rotavirus parent strain. The reassortants are propagated in Vero cells using standard tissue culture techniques.

RV5 vaccine is provided in a squeezable plastic dosing tube with a twist-off cap designed to allow for the vaccine to be administered directly to infants by mouth. Each tube contains a single 2-mL dose of the vaccine as a buffered-stabilized liquid solution.

The human rotavirus vaccine (RV1) is a G1 P1A[8] virus attenuated by passage in cell culture. RV1 is provided as a lyophilized powder that is reconstituted with a supplied diluent before administration.

Both rotavirus vaccines must be stored at refrigerator temperatures (2°C–8°C [35°F–46°F]) and protected from light. RV1 diluent may be stored at room temperature. The vaccines must not be frozen. The shelf life of properly stored vaccine is 24 months. RV5 should be administered as soon as possible after being removed from refrigeration. RV1 should be administered within 24 hours of reconstitution. Reconstituted RV1 may be stored at refrigerator or room temperature.

No studies have addressed the interchangeability of the rotavirus vaccines.

Immunogenicity and Efficacy

The immune correlates of protection from rotavirus infection and disease are not fully understood. In a large phase III clinical trial of RV5, an increase in titer of rotavirus group-specific serum IgA antibodies was used as one of the measures of the immunogenicity. Serum samples were obtained from a subset of study participants before they were immunized and approximately 2 weeks after they received the third dose. Seroconversion was defined as a threefold or greater increase in antibody titer from baseline. Seroconversion rates for IgA antibody to rotavirus were 95% among vaccine recipients and 14% among recipients of the placebo.⁶⁶⁰

The efficacy of RV5 was evaluated in two phase III trials.^{83,660} In these trials, the efficacy of RV5 after completion of a three-dose regimen against rotavirus gastroenteritis of any severity was 74%, and against severe rotavirus gastroenteritis, it was 98 percent. Efficacy was observed against all G1 to G4 and G9 serotypes, but relatively few non-G1 rotavirus cases were reported. RV5 reduced the incidence of office visits by 86%, emergency department visits by 94%, and hospitalizations for rotavirus gastroenteritis by 96%. The efficacy of RV5 in the second rotavirus season after immunization was 63% against rotavirus gastroenteritis of any severity and 88% against severe rotavirus gastroenteritis.

Neither breastfeeding nor concurrent administration of other childhood vaccines appears to diminish the efficacy of a three-dose series of RV5. The efficacy of RV5 between doses of a three-dose series and with less than three doses (i.e., incomplete regimen) was explored in post hoc analyses of the large efficacy study of RV5. The vaccine reduced the rates of combined hospitalizations and ED visits for G1 through G4 rotavirus gastroenteritis by 100% between doses 1 and 2 and 91% between doses 2 and 3. RV5 reduced the rates of rotavirus gastroenteritis regardless of serotype by 82% between doses 1 and 2 and 84% between doses 2 and 3.²³⁷

Phase III clinical trials of RV1 efficacy have involved more than 21,000 infants 6 through 12 weeks of age, primarily in two studies in Latin America and Europe.^{569,658} After completion of a two-dose RV1 regimen, the efficacy of rotavirus vaccine against severe rotavirus gastroenteritis (i.e., Latin American study) was 85%, and against any rotavirus gastroenteritis (i.e., European study), it was 87%. RV1 reduced hospitalization for rotavirus gastroenteritis by 85% to 100%, depending on the study. The efficacy of fewer than two doses is not known.

Adverse Events

Safety with respect to intussusception was evaluated for 71,725 subjects enrolled in phase III efficacy trials of RV5.^{83,660} For the prespecified 42-day postimmunization end point, six cases of intussusception were

observed in the RV5 group versus five cases of intussusception in the placebo group (multiplicity-adjusted relative risk, 1.6). The data did not suggest an increased risk of intussusception relative to placebo. Among vaccine recipients, no confirmed cases of intussusception occurred within the 42-day period after administration of the first dose, which was the period of highest risk for the previously licensed RRV-TV vaccine. No evidence of clustering of cases of intussusception was observed within a 7- or 14-day window after immunization for any dose. For the 1-year follow-up period after administration of the first dose, 13 cases of intussusception were observed in the RV5 group versus 15 cases of intussusception in the placebo group (multiplicity-adjusted relative risk = 0.9).

Some studies performed outside the United States detected a low level of increased risk of intussusception after rotavirus immunization shortly after the first dose. The level of risk observed in these postmarketing studies is substantially lower than the risk of intussusception after immunization with RotaShield, the previous rotavirus vaccine.^{100,524,655} US postmarketing studies have also identified a small increased risk of intussusception with RV5 and RV1, usually within a week after the first or second vaccine dose. This additional risk is estimated to range from about one case per 20,000 to 100,000 US infants who receive rotavirus vaccine.^{73,325,601,679,708}

Both vaccines are well tolerated and have a low reactogenicity profile when given alone. They do not cause clinically significant increases in reactogenicity when coadministered with other routine childhood vaccines.^{234,563} For both vaccines, the incidence of fever, vomiting, diarrhea, and irritability were measured in the clinical trials. For RV5, no significant difference versus placebo was observed in the incidence of fever or severe fever and irritability or severe irritability. A 3% increase in the incidence of diarrhea and vomiting was observed with RV5, but these symptoms were mild and did not require treatment.^{83,236,660} For RV1, no difference versus placebo was observed in the incidence of diarrhea, fever or severe fever, vomiting or severe vomiting, and irritability or severe irritability within 14 days of immunization with any dose.^{235,535,657,659} There was no statistically significant increased risk of death or other serious adverse events with either vaccine compared with placebo.

Vaccine virus shedding in stool has been documented for both rotavirus vaccines. Rotavirus shedding occurs in approximately 9% of RV5 recipients after the first dose but rarely after subsequent doses.²³⁶ For RV1, live rotavirus shedding in stool occurs in approximately 25% of recipients, with peak excretion occurring about day 7 after the first dose. With the use of more sensitive real-time PCR tests for rotavirus shedding, detection rates for viral shedding were demonstrated in 20% to 30% in recipients of RV5 and in 80% to 90% of those receiving RV1.^{355,611} Both vaccines have been transmitted from vaccine recipients to unvaccinated siblings, but no significant gastrointestinal symptoms were seen in the unvaccinated sibling after transmission.^{527,559} Shedding and transmission are not considered significant safety concerns because of the attenuated nature of the rotavirus vaccine strains and the lack of severe gastrointestinal symptoms after transmission.

In 2010, porcine circovirus or porcine circovirus DNA was detected in both rotavirus vaccines.^{68,297,413,469} There is no evidence that this virus is a safety risk or causes illness in humans.⁴¹²

Indications

Infants should receive three doses of RV5 administered orally at 2, 4, and 6 months of age or two doses of the RV1 at 2 and 4 months of age.^{24,217} The first dose should be administered when the child is between 6 and 14 weeks of age (i.e., on or before 14 weeks, 0 days of age). Subsequent doses should be administered at a minimum of 4-week intervals, and all doses of vaccine should be administered by the time the child is 32 weeks of age (i.e., on or before 32 weeks, 0 days).

Immunization should not be initiated for infants older than 14 weeks because of insufficient data on the safety of the first dose of rotavirus vaccine in older infants. Vaccine should not be administered after 8 months of age because of insufficient data on the safety and efficacy of rotavirus vaccine in infants after this age. For infants for whom the first dose of rotavirus vaccine is inadvertently administered off-label at 15 weeks or older, the rest of the rotavirus immunization series should be completed according to the schedule defined earlier

because timing of the first dose should not affect the safety and efficacy of the second and third doses.

The rotavirus vaccine series should be completed with the same product whenever possible. However, vaccination should not be deferred if the product used for a prior dose or doses is not available or is not known. In this situation, the provider should continue or complete the series with the product that is available. If any dose in the series was RV5 (RotaTeq) or the vaccine brand used for any prior dose in the series is not known, a total of three doses of rotavirus vaccine should be administered. Infants documented to have had rotavirus gastroenteritis before receiving the full course of rotavirus immunizations should still start or complete the three-dose schedule because the initial infection frequently provides only partial immunity.

Infants who are being breastfed can receive rotavirus vaccine. Like other childhood vaccines, rotavirus vaccine can be administered to infants with transient, mild illnesses, with or without low-grade fever.⁴⁰⁸ Rotavirus vaccine can be administered together with DTaP, Hib, IPV, hepatitis B, and pneumococcal conjugate vaccines.

The AAP and ACIP support immunization of preterm infants under the following conditions. The infant is at least 6 weeks of age, the infant is clinically stable, and the first dose of vaccine is given at the time of discharge or after the infant has been discharged from the hospital nursery.

Infants living in households with people who have or are suspected of having an immunodeficiency disorder or impaired immune status or with a pregnant woman can be immunized. To minimize potential virus transmission, all members of the household should employ measures such as good handwashing after contact with the feces of the immunized infant (e.g., after changing a diaper) for at least 1 week after the first dose of rotavirus vaccine has been given.

An infant who regurgitates, spits out, or vomits during or after receiving a dose of rotavirus vaccine should not have that dose readministered. The infant can receive the remaining recommended doses of rotavirus vaccine at appropriate intervals. If a recently immunized child is hospitalized for any reason, no precautions other than standard precautions need be taken to prevent the spread of vaccine virus in the hospital setting.

Contraindications and Precautions

Rotavirus vaccine should not be administered to infants who have severe hypersensitivity to any component of the vaccine or individuals who have experienced a serious allergic reaction to a previous dose of rotavirus vaccine.^{24,217} The RV1 oral applicator contains latex rubber. RV5 may be preferred for children at high risk for latex sensitization.

Practitioners should consider the potential risks and benefits of administering rotavirus vaccine to infants with known or suspected altered immunocompetence. Children and adults who are immunocompromised because of congenital immunodeficiency, bone marrow transplantation, or solid organ transplantation sometimes experience severe, prolonged, and even fatal rotavirus gastroenteritis. However, no safety or efficacy data are available for the administration of rotavirus vaccine to infants who are potentially immunocompromised with the exception of infants with severe combined immune deficiency (SCID). SCID is a contraindication for the use of both rotavirus vaccines.¹⁵⁷ Gastroenteritis, including severe diarrhea and prolonged shedding of vaccine virus, has been reported in infants who were administered live oral rotavirus vaccines and later identified as having SCID.⁶¹

Rotavirus vaccine should not be administered to infants with acute, moderate to severe gastroenteritis until the condition improves. Rotavirus vaccine has not been studied among infants with concurrent acute gastroenteritis, in whom its immunogenicity and efficacy theoretically can be compromised. Infants with moderate to severe illness should be immunized as soon as they have recovered from the acute phase of the illness.

Infants with preexisting chronic gastrointestinal conditions and who are not undergoing immunosuppressive therapy should benefit from rotavirus vaccine immunization, and the benefits outweigh the theoretical risks. However, the safety and efficacy of rotavirus vaccine have not been established for infants with these preexisting conditions (e.g.,

congenital malabsorption syndromes, Hirschsprung disease, short-gut syndrome, persistent vomiting of unknown cause).

A history of intussusception is a contraindication for the use of both rotavirus vaccines.¹⁶⁵ Some data suggest that infants with a history of intussusception may be at higher risk for a repeat episode than other infants.

Rubella Vaccine

Rubella is a viral disease that usually manifests as a mild febrile rash illness in adults and children; however, 20% to 50% of infected people are asymptomatic. Rubella can have severe adverse effects on the fetuses of pregnant women who contract the disease during the first trimester of pregnancy. It causes a wide range of congenital defects known as congenital rubella syndrome (CRS). The primary objective of the rubella vaccination program is to prevent intrauterine rubella infection. The primary strategies for rubella control in the United States are universal childhood vaccination, prenatal screening of pregnant women for rubella immunity, and vaccination of rubella-susceptible women after delivery.

In the prevaccine era, epidemics of rubella occurred every 6 to 9 years, with the last major epidemic in the United States taking place in 1964 through 1965.⁶⁹⁴ The incidence of reported cases of rubella fell sharply after routine rubella immunization of young children was initiated in the United States in 1969. From the estimated 2 million cases per year in the prevaccine era, fewer than 1000 cases were reported in 1983.

During 1989 through 1991, a resurgence of rubella occurred, primarily because of outbreaks among unvaccinated adolescents and young adults who initially were not recommended for vaccination and in religious communities with low rubella vaccination coverage.¹⁰⁷ As a result of the rubella outbreaks, two clusters of approximately 20 CRS cases occurred.^{424,475} Outbreaks during the mid-1990s occurred in settings where young adults congregated and involved unvaccinated people who belonged to specific racial or ethnic groups.¹²¹ Further declines occurred as rubella vaccination efforts increased in other countries in the WHO Region of the Americas. From 2001 through 2004, reported rubella and CRS cases were at an all-time low, with an average of 14 reported rubella cases a year, four CRS cases, and one rubella outbreak (defined as three or more cases linked in time or place).⁵⁵⁰

In October 2004, 35 years after initiation of the rubella immunization program, an independent panel of international experts was convened by the CDC to assess progress toward elimination of rubella and CRS. Based on data showing fewer than 25 cases of rubella reported each year since 2001, at least 95% vaccination coverage among school-aged children, an estimated 91% population immunity, adequate surveillance to detect rubella outbreaks, and a pattern of virus genotypes consistent with virus originating in other parts of the world, panel members concluded unananimously that rubella was no longer endemic in the United States.⁵⁴⁹

Rubella continues to be endemic in many parts of the world. Internationally imported rubella cases may give rise to indigenous transmission. From 2005 through 2011, a median of 11 rubella cases was reported each year in the United States (range, 4–18). Two rubella outbreaks involving three cases and four total CRS cases were reported. Among the 67 rubella cases reported from 2005 through 2011, a total of 28 cases (42%) were known importations.⁵⁵¹ In 2011, an expert panel reviewed available data and unanimously agreed that rubella elimination had been maintained in the United States.⁵²⁰

From 2012 through 2015 a total of 29 rubella cases (range, 5–9 cases/year) and 6 CRS cases (range, 1–3 cases/year) have been reported in the United States. The United States needs to continue its vigilance against rubella and CRS by maintaining high vaccination rates among children; ensuring vaccination among women of childbearing age, especially women born outside the United States; continuing surveillance of rubella and CRS; and responding rapidly to any outbreak.¹⁴⁶

Preparations

Since 1979, RA 27/3 (*Rubella abortus*, 27th specimen, third extract) vaccine, prepared in human diploid tissue culture, has been the only vaccine available in the United States; it replaced the earlier HPV-77 and Cendehill vaccines. RA 27/3 induces higher antibody titers and

more closely parallels the immune response after natural infection than did previous vaccines.^{314,420,425,515,676} Two rubella-containing vaccines, MMR and MMRV, are available. Both vaccines should be kept at 2°C to 8°C (35.6°F–46.4°F) or colder during storage and should be protected from light to avoid inactivation of the virus. After reconstitution, the vaccine should be used within 8 hours.

Immunogenicity and Efficacy

Immunization with rubella vaccine induces humoral and cell-mediated immunity. At least 95% of susceptible vaccinees 12 months or older develop antibody titers that are protective after a single dose of vaccine.^{275,281,288,607,639,676} After a second dose of rubella vaccine, approximately 99% had detectable rubella antibody and approximately 60% had a fourfold increase in titer.^{372,404,423}

Follow-up studies indicate that one dose of rubella vaccine can provide long-lasting immunity. Vaccine-induced rubella antibodies have persisted in more than 90% of vaccinees 16 years after receiving a single dose of vaccine, but antibody levels decreased over time.^{190,345,353,421,540} Although levels of vaccine-induced rubella antibodies can decrease over time, data from surveillance of rubella and CRS suggest that waning immunity with increased susceptibility to rubella disease does not occur. Among people receiving two doses, approximately 91% to 100% had detectable antibodies 12 to 15 years after receiving the second dose.^{227,423}

Outbreaks of rubella in vaccinated populations are rare. Studies demonstrate rubella vaccine is approximately 97% effective in preventing clinical disease after a single dose (range, 94–100%).^{69,225,283}

Lifelong protection against clinical reinfection or asymptomatic viremia, or both, usually results from a single dose of vaccine given early in childhood. In some cases, vaccinees exposed to natural rubella developed a rise in antibody titer unassociated with clinical symptoms. Reinfection is associated only rarely with viremia. Significant pharyngeal shedding also is observed infrequently. Person-to-person transmission, however, has not been reported. Reinfection caused by wild-type rubella virus also may be observed in individuals with previous natural rubella infection. The risk of CRS developing from rubella reinfection during pregnancy is extremely low.⁵⁶¹

Adverse Events

Rubella vaccines usually are well tolerated. The most frequent complaints after vaccination are fever, lymphadenopathy, or rash, which occur in 5% to 15% of children 5 to 12 days after receiving vaccination.⁴⁴ Transient peripheral neuritis (i.e., paresthesia and pain in the arms and legs) has been observed uncommonly, primarily in older age groups.⁵⁸⁰

Approximately 3% of children have transient joint manifestations, including arthralgia and, less commonly, arthritis 1 to 3 weeks after being immunized. Although 25% of women report having joint pain after being vaccinated, arthritis with objective clinical findings lasting less than 10 days occurs in 13% to 15%. Cases of persistent or recurrent joint symptoms have been reported but are rare events. In 1992, the IOM reviewed the existing data on rubella and adverse joint events and concluded that the evidence available was consistent with a causal relationship between rubella vaccination and chronic arthritis in women, although data on current vaccine strains are limited.³⁵⁴ The incidence of joint manifestations after immunization is lower than that after natural infection at the corresponding age.

Rubella revaccination is well tolerated, even among college-aged and older vaccinees, and it is associated with a much lower incidence of adverse reactions than primary rubella immunization of young adult populations. Reported rates of joint-related complaints of 4% to 18% after revaccination are lower than those reported after primary vaccination.^{186,590}

Indications

Live virus rubella vaccine usually is recommended for all children 12 months or older. It is given as MMR or MMRV when children are 12 to 15 months of age.^{44,471} A second dose of rubella vaccine administered as MMR or MMRV is given at the time they enter school, usually 4 to 6 years of age, according to recommendations for routine measles immunization. The vaccine should be provided to previously unimmunized preschool-aged children or older schoolchildren despite a

history of having clinical rubella, unless serologic tests confirm immunity.

Emphasis should be placed on the immunization of the postpubertal male and female population, especially college students and those in the military. Rubella vaccine also should be administered to adolescent girls and women of childbearing age who lack a history of previous vaccination. Other opportunities for immunization include premarital screening, routine gynecologic examinations, visits for neonatal and well-child care, or other medical visits. The immediate postpartum period is an excellent time for giving immunizations. Rubella vaccine can be given after administration of anti-Rho(D) immune globulin, but serologic testing to determine whether seroconversion has occurred should be performed at least 8 weeks after vaccination. When practical, potential vaccinees may be screened for susceptibility. However, vaccination of girls and women of childbearing age is justifiable and may be preferable, without previous serologic testing of women not known to be pregnant.

Adults in the United States who were born in countries where rubella vaccination was not offered are at higher risk for contracting rubella and having infants with CRS. Health care practitioners who treat foreign-born adults should document the rubella immunity of these patients with a written record of rubella-containing vaccine or by serologic testing. Susceptible adults, especially women of childbearing age, should be vaccinated. During rubella outbreaks, all susceptible people who have no contraindications to rubella vaccine should be identified and vaccinated.

Precautions and Contraindications

Specific contraindications to the administration of live rubella vaccine include pregnancy; severe febrile illness; known history of anaphylactic reaction to rubella vaccine, gelatin, or neomycin, which are contained in the vaccine; and immunodeficiency conditions (i.e., malignancy, primary immunodeficiency disease, immunosuppressive or corticosteroid therapy, and radiation therapy).^{44,471} People with mild immunosuppression, such as those with asymptomatic HIV infection or those taking short-term or low-dose corticosteroids, may be vaccinated.

Postpubertal women of childbearing age who are known to be pregnant or who are attempting to become pregnant should not be vaccinated. Vaccinated women should be counseled about the need to avoid pregnancy for 28 days after receiving vaccination.⁴⁷¹ Although pregnancy is a contraindication to administering rubella vaccination, the maximal theoretical risk to the fetus is estimated to be 2.6%.⁵⁴⁵ From 1979 until 1989, the CDC registered 321 susceptible women who inadvertently had received RA 27/3 rubella vaccine within 3 months before or after conception and carried their pregnancies to term. None of their infants had defects compatible with CRS, although 2% had serologic evidence of intrauterine infection.¹¹³ Because rubella virus has been isolated from the products of conception of women vaccinated during pregnancy, continued caution with respect to vaccination during pregnancy is advised. However, the evidence available indicates that rubella vaccination inadvertently given during pregnancy ordinarily does not represent a reason to consider interruption of pregnancy.

Although vaccine virus may be isolated from the pharynx, vaccinees do not transmit rubella to others, except in the case of a vaccinated breastfeeding mother. In this situation, the infant may be infected through breast milk, and a mild rash illness may develop, but serious adverse effects have not been noted. Infants infected through breastfeeding respond normally to rubella vaccination at 15 months of age. Breastfeeding is not a contraindication to receiving rubella vaccination.

Concern about potential transmission of disease from immunized children to susceptible contacts, including pregnant women, has not been supported by studies of susceptible household contacts. Susceptible children whose household contacts are pregnant may be vaccinated.

People with a history of thrombocytopenia may experience thrombocytopenia after receipt of MMR vaccine. The decision to vaccinate should depend on the benefits of immunity compared with the risk of recurrence or exacerbation of thrombocytopenia after vaccination or during natural infection with measles or rubella.

Rubella vaccine should not be given during an interval beginning 2 weeks before and extending 3 months after the administration of

immune globulin or blood transfusion. Because rubella vaccine usually is given as MMR or MMRV, and evidence suggests that high doses of immune globulin preparations can inhibit the immune response to measles vaccine for 3 or more months, depending on the dosage, rubella vaccination with MMR or MMRV necessitates deferral for longer periods (see [Measles Vaccine](#)).^{44,471,603}

Tetanus Toxoid

The efficacy of active immunization against tetanus was demonstrated most dramatically in military personnel during World War II, when tetanus toxoid virtually eliminated tetanus in injured servicemen. Since the 1940s, routine immunization of civilians in the United States with tetanus toxoid has been successful in almost eliminating tetanus. In most cases, disease has been reported in unimmunized or inadequately immunized individuals.¹¹⁴ The primary three-dose series of a tetanus toxoid-containing vaccine confers protective immunity for 10 years or longer.^{90,405}

Without a tetanus booster, immunity wanes over time. The potential for occurrence of tetanus is indicated by the significant number of adults in the United States who lack protective concentrations of serum antibody.²⁸⁹ Between 2001 and 2008, 233 cases of tetanus were reported in the United States with a case-fatality rate of 13%. In 22 of these cases, the children were between the ages of 5 and 19 years, and 16 had received one or no tetanus immunizations. There were no deaths in this age group.¹⁶⁸

Neonatal tetanus also has been almost eliminated in the United States. However, it is a leading cause of morbidity in neonates in developing countries. As a result, global elimination of neonatal tetanus remains a goal of the WHO. Because the spores of tetanus are distributed widely in the environment, the risk of infection among the unimmunized is constant. This is a fact not necessarily appreciated by parents who refuse immunization in the belief that widespread immunization in the general population will confer some protection on the unimmunized, as was demonstrated by two cases of tetanus in children in Oklahoma in 2012.^{246,375}

Preparations

Tetanus toxoid is prepared by formaldehyde treatment of *Clostridium tetani* toxin.^{90,405} It has been prepared in fluid and aluminum salt-adsorbed preparations, but in the United States, only the latter is available. Fluid toxoid preparations result in a significantly shorter duration of immunity than that induced by aluminum-adsorbed antigens; therefore, adsorbed antigens are recommended.

Tetanus toxoid is available in combination with diphtheria toxoid and acellular pertussis vaccine (DTaP) for routine administration to infants and children younger than 7 years and for adolescents and adults 11 years or older as a single booster (Tdap). For all people for whom pertussis vaccine is contraindicated, tetanus toxoid is combined with diphtheria toxoid as DT or Td (see [Diphtheria Toxoid](#)).

The first two Tdap vaccines approved for use in adolescents and adults in the United States—Boostrix (GlaxoSmithKline Biologicals) and Adacel (Sanofi Pasteur)—were licensed in 2005. Preparations of DT, Td, and Tdap are identical in the amounts of tetanus toxoid they contain, but they differ in the quantity of diphtheria toxoid. The dose of Tdap is the same as that of DT or Td (0.5 mL) and is administered intramuscularly.

Immunogenicity and Efficacy

Adequate primary immunization provides sufficient protective titers of antitoxin for at least 10 years and ensures prompt, anamnestic responses to subsequent booster injections. Immune response to tetanus toxoid was measured after administration of each adult Tdap vaccine and compared with that elaborated after Td vaccine. Seroprotective anti-tetanus antibody concentrations, defined as a titer 0.1 IU/mL or greater, and booster response rates to tetanus were determined to be noninferior after vaccination with Tdap compared with Td vaccination.^{90,405}

Adverse Events

Local reactions of pain, swelling, and induration can occur, but these reactions in children usually are attributable to the pertussis component

contained in the vaccine rather than to response to tetanus toxoid.⁴⁷ Hypersensitivity reactions can occur in adolescents and adults but rarely are severe. Neurologic reactions occurring after the administration of tetanus toxoid are rare events. Reactions include brachial neuritis and Guillain-Barré syndrome.

Regarding adverse reactions reported after Tdap, vaccination with Boostrix was associated with a statistically higher rate of moderate to severe headache compared with Td, and that with Adacel was associated with higher rates of mild injection site pain and low-grade fever compared with the Td vaccine. No serious adverse events have been reported for Boostrix. Two cases of serious adverse events (both characterized as neuropathic reactions) in adults possibly related to having received Adacel (none reported in adolescents) have been reported, and in both cases, symptoms resolved completely within several days.^{90,405}

Indications

Preexposure indications. For primary immunization, doses of tetanus toxoid provided as DTaP should be administered when the child is 2, 4, and 6 months of age.^{21,47,90} A fourth dose is given 6 to 12 months after the third dose (i.e., at 12 to 18 months of age) to maintain adequate serum antibody concentrations for the ensuing preschool years. For children younger than 7 years not immunized in infancy, an initial dose of DTaP is given with subsequent doses 2, 4, and 10 to 16 months later, followed by a single booster dose at age 4 to 6 years, just before school entry.

In 2005, the FDA licensed two Tdap vaccines for routine use in adolescents and adults. Adacel (Sanofi Pasteur) is approved for people 11 to 64 years of age, and Boostrix (GlaxoSmithKline Biologicals) is approved for children and adolescents 10 years or older. These vaccines are approved for one-time use only in individuals who have previously completed their primary vaccination series with DTP or DTaP as a substitute for their next Td booster.¹⁷¹ The preferred age for Tdap vaccination is 11 to 12 years. Catch-up vaccination with Tdap is encouraged for adolescents 13 to 18 years old who completed their primary series with DTP or DTaP and have not received a Td or Tdap booster.

Adolescents 11 through 18 years of age who received Td but not Tdap are encouraged to receive a single dose of Tdap to provide protection against pertussis if they have completed the recommended childhood DTP/DTaP immunization series. Tdap should be administered regardless of the interval since the last tetanus or diphtheria toxoid-containing vaccine. Although longer intervals between Td and Tdap may decrease the occurrence of local reactions, the benefits of protection against pertussis outweigh the potential risk of adverse events.^{47,171} Every 10 years thereafter, tetanus booster should be provided by Td.

Adolescents between the ages of 11 and 18 years who have never been vaccinated against tetanus, diphtheria, or pertussis should receive Tdap initially, followed by Td for the subsequent two doses 4 or more weeks and then 6 to 12 months later. For children between the ages of 7 and 10 years who have not been vaccinated previously, Tdap vaccine should substitute an initial dose of Td in the catch-up series, followed by two subsequent doses of Td vaccine at 4 or more weeks, and 6 to 12 months after the previous dose.^{47,171} Interruption of the recommended schedule or delay in administering subsequent doses during primary immunization does not reduce immunity.

Antepartum indications. In areas of the world where the risk of acquiring neonatal tetanus is significant, previously unimmunized, pregnant women should receive two antepartum doses of a tetanus toxoid-containing vaccine spaced at least 4 weeks apart. The second dose should be given at least 2 weeks before delivery. The woman should complete the three-dose series in 6 to 12 months.^{318,405} Tdap should be substituted for the first Td dose if Tdap has not been administered previously. In the United States, immunization with Tdap is recommended during each pregnancy, preferably in the early third trimester.^{171,175} If vaccination is not provided before delivery or during pregnancy, women who have not received Tdap vaccine previously should receive a single dose of Tdap in the immediate postpartum period, preferably before being discharged from their hospital or birthing center.

Postexposure wound management. The potential need for immunoprophylaxis is an integral aspect of wound management at the time of trauma or injury. The recommended use of tetanus toxoid in

TABLE 245.17 Recommended Tetanus Prophylaxis in Wound Management

History of Tetanus Toxoid	CLEAN, MINOR WOUNDS		ALL OTHER WOUNDS ^a	
	Td or Tdap ^b	TIG	Td or Tdap ^b	TIG
<3 doses or unknown	Yes	No	Yes	Yes
≥3 doses	No ^c	No	No ^d	No

^aIncluding wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

^bFor children <7 y; diphtheria–tetanus–acellular pertussis (DTaP) or diphtheria–tetanus (DT) (depending on vaccine status of patient) is preferred to tetanus toxoid (TT) alone. Tdap is preferred over Td for underimmunized children ≥7 y who have not received Tdap previously.⁴⁷ Td is preferred to TT for adolescents who received Tdap previously or when Tdap is not available.

^cYes if ≥10 y since last tetanus-containing vaccine dose.

^dYes if ≥5 y since last tetanus-containing vaccine dose. More frequent boosters are not needed and can accentuate side effects.

Td, Tetanus–diphtheria; Tdap, tetanus–diphtheria–acellular pertussis; TIG, tetanus immune globulin.

addition to tetanus immune globulin at the time of injury is given in Table 245.17. To ensure adequate immunity, children and adults receiving tetanus toxoid for wound management should be given age-appropriate preparations of vaccines containing diphtheria and pertussis, unless contraindicated, and tetanus toxoid. Tdap is preferred over Td if the person has not received Tdap previously.^{47,171} Specific recommendations depend on the individual's immunization status, the nature of the wound, and the duration of time between when the injury occurred and evaluation and treatment were undertaken.

After prophylaxis is provided, primary immunization should be completed subsequently in those lacking the recommended number of doses. This conservative approach to the frequent administration of booster doses of tetanus toxoid in wound management for previously immunized people is supported by the prolonged immunity from tetanus vaccination and the increased incidence of hypersensitivity reactions associated with receipt of frequent booster injections.⁵²⁹ Patients convalescing from tetanus infection should complete active immunization because infection often does not confer immunity.

Precautions and Contraindications

A history of having an immediate, severe hypersensitivity reaction to tetanus toxoid–containing preparations that is severe or anaphylactic in type is a contraindication to receiving further vaccination.^{21,47,90,405} People who experience Arthus-type hypersensitivity reactions after receiving tetanus toxoid or temperature greater than 39.4°C (103°F) after a previous dose of a tetanus toxoid–containing preparation usually have high serum tetanus antitoxin concentrations and should not be given doses of Td more frequently than every 10 years, even if they have a tetanus-prone wound.⁴⁷ If an anaphylactic reaction to a previous dose of tetanus toxoid is suspected, intradermal skin testing may be helpful in determining whether to discontinue tetanus toxoid vaccination.³⁶⁷

Because tetanus toxoid administration has been associated with recurrence of Guillain-Barré syndrome in rare cases,³⁵⁹ the decision to give additional doses in people with a history of this syndrome within 6 weeks after receipt of tetanus toxoid should be based on consideration of the benefit of revaccination and the comparative risk of recurrence of Guillain-Barré syndrome.¹²⁸ No physician-diagnosed cases of anaphylaxis, Arthus reactions, or Guillain-Barré syndrome in any adolescent or adult after either Tdap vaccine have been reported.

Varicella Vaccine

In the prevaccine era, varicella was endemic in the United States and virtually all people acquired varicella by the time they reached adulthood. Varicella infection was responsible for an estimated 4 million cases, 11,000 hospitalizations, and 100 deaths each year in the United States.¹³³

Approximately 90% of cases were children, with the highest incidence for children 1 to 6 years old.

After introduction and routine use of varicella vaccine in 1995, the incidence of varicella fell by 90%, deaths from varicella declined by 66%, and rates of hospitalization for varicella decreased by 80%.^{322,504,715} However, a high frequency of breakthrough varicella (i.e., chickenpox occurring in a previously vaccinated person) in immunized children and continuing outbreaks of varicella in schools and in childcare centers occurred, despite high rates of vaccination.²⁹² Studies showed that over time the vaccine's effectiveness was less than 90%,⁵⁹² and in one study of healthy children, the rate of seroconversion after one dose of the vaccine was only 76%.⁴⁷⁷ In June 2006, the CDC and AAP recommended a routine two-dose varicella vaccination policy for children (i.e., first dose at 12 to 15 months and second dose at 4 to 6 years) and catch-up vaccinations for children, adolescents, and adults who previously had received only one dose.^{23,451}

Since recommendation of a routine second dose of vaccine in 2006, the incidence of varicella has declined further among children. Data show that administration of two doses of varicella vaccine is associated with higher antibody titers, presumably offering better protection from varicella.⁴¹⁵ Results from a controlled study of the effectiveness of two doses of varicella vaccine indicated that administration of two doses was highly effective in preventing varicella in the first 2.5 years after implementation of the two-dose schedule to prevent disease.⁵⁹⁵ Odds of developing varicella were 95% lower for children who received two doses compared with one dose of varicella vaccine.

Preparations

Three varicella-containing vaccines are approved for use in the United States: varicella vaccine (Varivax), combination MMRV vaccine (ProQuad), and herpes zoster vaccine (Zostavax). Varicella vaccine was licensed in the United States in 1995. It is a preparation of the Oka strain of varicella-zoster virus (VZV) obtained from the vesicle fluid of a healthy child with varicella that has been attenuated by serial propagation in human embryo lung fibroblasts, guinea pig embryonic cells, and human diploid cell cultures. The vaccine contains trace amounts of neomycin, fetal bovine serum, sucrose, residual components of human diploid (MRC-5) cells, and gelatin. The vaccine does not contain preservatives.

Varicella vaccine is lyophilized and stored frozen at –15°C or colder until reconstituted. Any freezer that reliably maintains an average temperature of –15°C and has a separate sealed freezer door is acceptable for storing vaccine. The vaccine also may be stored at refrigerator temperature (2°C–8°C) for as long as 72 hours before reconstitution. Vaccine stored at 2°C to 8°C that is not used within 72 hours should be discarded. Reconstituted vaccine should be stored at room temperature and discarded if it is not used within 30 minutes.

In September 2005, a combined live attenuated MMRV vaccine was licensed for use in children 12 months through 12 years of age.¹⁴⁸ The attenuated measles, mumps, and rubella vaccine viruses in MMRV are identical and of equal titer to those in the MMR vaccine. The titer of Oka/Merck VZV is higher in MMRV vaccine than in single-antigen varicella vaccine. Each 0.5-mL dose contains a small quantity of hydrolyzed gelatin, human albumin, residual components of MRC-5 cells, neomycin, bovine calf serum, and other buffer and media ingredients. Unlike single-antigen varicella vaccine, MMRV vaccine cannot be stored at refrigerator temperature. MMRV vaccine must be stored frozen at an average temperature of –15°C or lower for up to 18 months. After reconstitution, the vaccine should be used immediately to minimize loss of potency and should be discarded if it is not used within 30 minutes. The diluent should be stored separately at room temperature or in the refrigerator. MMRV vaccine contains no preservative.

In May 2006, the FDA approved herpes zoster vaccine for use in people 60 years or older. No indications for use of this vaccine in children exist.

Immunogenicity and Efficacy

Varicella vaccine is highly immunogenic in susceptible children. Seroconversion has occurred in more than 96% of children 12 months to 12 years of age after one dose of vaccine.⁶⁸⁵ Preexisting antibody, if

present at 12 months of age, does not appear to interfere with antibody response. As with other viral vaccines, the antibody response after immunization is lower than that from natural disease. Adolescents and adults have age-related decreases in the ability to develop a primary response to varicella virus.²⁹¹ Seroconversion rates of 78% to 82% after one dose and 99% after two doses have been reported in those older than 12 years.^{291,685}

In studies in the United States and Japan, serum antibodies to varicella have been detected for as long as 10 to 20 years after immunization in more than 95% of immunized children.^{59,376} Antibody concentrations have persisted for at least 1 year in 97% of adults and adolescents who were administered two doses of vaccine 4 to 8 weeks apart.²⁹¹ Cell-mediated immunity to VZV has been detected in 87% of children and 94% of adults 5 years after vaccination.⁷¹⁴

MMRV vaccine was licensed on the basis of equivalence of immunogenicity of the antigenic components, rather than clinical efficacy. Clinical studies involving healthy children 12 to 23 months of age indicated that those who received a single dose of MMRV vaccine developed levels of antibody to measles, mumps, rubella, and varicella similar to those of children who received MMR and varicella vaccines concomitantly at separate injection sites.⁴¹⁴

Varicella vaccine has been demonstrated to be highly effective in preventing varicella in children and in reducing the severity of infection if they do become infected. In prelicensure clinical trials, vaccine was 70% to 90% effective in preventing varicella and more than 95% effective in preventing severe disease.^{416,674} Several postlicensure studies have shown similar results, with vaccine effectiveness ranging from 83% to 100% in preventing varicella and 87% to 100% in preventing severe disease.^{195,365,654} In follow-up studies, chickenpox developed in 0.2% to 2.3% of vaccinated children per year after exposure to wild-type varicella virus, a rate that does not seem to increase with length of time after immunization.⁶⁶¹ These vaccine failure cases are mild, with fewer skin lesions, lower rates of fever, and faster recovery, and they are less contagious than are moderate to severe cases of varicella.^{75,593,661,671} These infections have been called *breakthrough varicella*.

Although findings of some studies have suggested otherwise, most investigations have not identified time since vaccination as a risk factor for breakthrough varicella. Some investigations have identified asthma, use of corticosteroids, and vaccination at younger than 15 months as risk factors for breakthrough varicella.^{251,286,365,646,656} Breakthrough varicella infection can result from several factors, including interference of vaccine virus replication by circulating antibody, impotent vaccine resulting from storage or handling errors, or inaccurate record keeping. Interference from live viral vaccine administered before varicella vaccine can reduce vaccine effectiveness.

A study of 115,000 children in two health maintenance organizations from 1995 to 1999 found that children who received varicella vaccine less than 30 days after MMR vaccination had a 2.5-fold increased risk of breakthrough varicella compared with those who received varicella vaccine before, simultaneously with, or more than 30 days after receiving MMR.⁶⁵⁶ Inactivated vaccines (i.e., DTaP, Hib, IPV, and hepatitis B) and OPV did not increase the risk of breakthrough varicella if they were administered less than 30 days before administration of varicella vaccine.

For adults and adolescents who have seroconverted, varicella vaccine provides protective efficacy rates of approximately 70% after household exposure. In the remaining 30%, attenuated disease with fewer skin lesions and little or no systemic toxicity develops, as in children.²⁹¹

Adverse Events

Varicella vaccine produces relatively few adverse reactions.^{596,693} The most common adverse reactions that occur after receipt of varicella vaccine are local reactions, such as pain, soreness, erythema, and swelling. Based on information from the manufacturer's clinical trials of varicella vaccine, local reactions after receiving the first dose are reported by 19% of children and by 24% of adolescents and adults.^{596,693} These local adverse reactions usually are mild and self-limited.

A varicella-like rash at the site of injection is reported by 3% of children and by 1% of adolescents and adults after receipt of the second dose. In both circumstances, a median of two lesions has occurred.

These lesions usually occur within 2 weeks and usually are maculopapular rather than vesicular.^{596,693}

In postlicensure studies, the adverse event most frequently reported is a mild vesicular rash that occurs in approximately 5% of vaccinees.^{133,290} Most of these generalized rashes occur within 3 weeks, and most are maculopapular. In one study, vesicular rashes that occurred within 2 weeks of vaccination were more likely to be caused by wild-type varicella, whereas rashes that occurred more than 2 weeks after vaccination were more likely to be caused by the Oka vaccine strain.⁵⁹⁶

Systemic reactions can occur. Fever within 42 days of vaccination is reported by 15% of children and 10% of adolescents and adults. Most of these episodes of fever have been attributed to concurrent illness rather than to the vaccine.

Clinical trials of MMRV that compared events that occurred within 42 days of receiving MMRV or MMR and varicella vaccine separately in different anatomic sites found the frequencies of local reactions and generalized varicella-like rash similar to those described for varicella vaccine.⁴¹⁴ A temperature of 38.9°C (102°F) or higher within 42 days of vaccination was more common in the MMRV group (22%) than in the group that received MMR and varicella vaccine at different sites (15%). A measles-like rash also occurred more frequently in MMRV recipients (3%) than in those receiving separate injections (2%). Fever and measles-like rash usually occurred 5 to 12 days after receipt of vaccination. In a postlicensure study, an increased risk of seizure was seen among children 12 to 23 months of age receiving MMRV vaccine compared with those who received MMR and varicella vaccines given separately in the 7- to 10-day postvaccination period.³⁹⁴

Varicella vaccine is a live virus vaccine and may result in a latent infection, similar to that caused by wild-type varicella virus. Consequently, zoster caused by the vaccine virus has been reported, mostly among vaccinated children. Based on reports to VAERS, the rate of herpes zoster after varicella vaccination is 2.6 cases per 100,000 vaccine doses distributed.¹³³ The incidence of herpes zoster after natural varicella infection in healthy people younger than 20 years is 68 cases per 100,000 person-years,³²⁰ and for all ages, it is 215 cases per 100,000 person-years.²⁴² However, the latter rates should be compared cautiously because they are based on populations monitored for longer periods than the vaccinees were monitored.

Cases of herpes zoster have been confirmed by PCR to be caused by vaccine virus and wild-type virus, a finding suggesting that some herpes zoster disease in vaccinees may result from antecedent natural varicella infection.^{133,330} Most cases of herpes zoster that occur after administration of vaccine have been mild and have not been associated with complications such as postherpetic neuralgia.

Transmission of the vaccine virus occurs rarely and most often from immunocompromised vaccinees. Of the 15 million doses of varicella vaccine distributed, on only three occasions has transmission from immunocompetent people been documented by PCR analysis.^{418,574} All three cases resulted in mild disease without complications. In one case, a child 12 months old transmitted the vaccine virus to his pregnant mother.^{437,574} The mother elected to terminate the pregnancy, but fetal tissue tested by PCR was negative for varicella vaccine virus. The other two documented cases involved transmission from healthy children 1 year of age to a healthy sibling 4.5 months of age and to a healthy father.¹³³ Transmission also has occurred from a person with herpes zoster caused by vaccine strain virus.⁹⁴ Transmission has not been documented in the absence of a vesicular rash after vaccination. No evidence indicates reversion to virulence of the vaccine strain during transmission; siblings of leukemic vaccine recipients who acquired vaccine virus had mild rash in 75% of cases and symptomless seroconversion in 25%.⁵⁵

Indications

Monovalent varicella vaccine and MMRV have been licensed for use for healthy children 12 months through 12 years of age.^{26,23,49,155,450,451} Children in this age group should receive two 0.5-mL doses of varicella vaccine administered subcutaneously, separated by at least 3 months. The recommendation for at least a 3-month interval between doses is based on the design of the studies evaluating two doses in this age group; if the second dose inadvertently is administered between 28 days

and 3 months after the first dose, the second dose does not need to be repeated.

All healthy children routinely should receive the first dose of varicella-containing vaccine at 12 through 15 months of age. The second dose of vaccine is recommended routinely when children are 4 through 6 years of age (i.e., before a child enters kindergarten or first grade) but can be administered at an earlier age. Because of the minimal potential for increased febrile seizures after the first dose of MMRV vaccine in children 12 through 15 months of age, the AAP and ACIP recommend a choice of MMR plus monovalent varicella vaccine or MMRV for toddlers receiving their first immunization of this kind.^{26,450} Parents should be counseled about the rare possibility of their child developing a febrile seizure 1 to 2 weeks after immunization with MMRV for the first immunizing dose. For the second dose at 4 through 6 years of age, MMRV usually is preferred over MMR plus monovalent varicella to minimize the number of injections. Varicella vaccine should be administered to all children in this age range unless there is evidence of immunity to varicella or a contraindication to administration of the vaccine.

A catch-up second dose of varicella vaccine should be offered to all children 7 years and older who have received only one dose. A routine health maintenance visit at 11 through 12 years of age is recommended for all adolescents to evaluate immunization status and administer necessary vaccines, including the varicella vaccine.

Individuals 13 years or older without evidence of immunity should receive two 0.5-mL doses of varicella vaccine separated by at least 28 days. The recommendation for at least a 28-day interval between doses is based on the design of the studies evaluating two doses in this age group. For people who previously received only one dose of varicella vaccine, a second dose is necessary. Only monovalent varicella vaccine is licensed for use in this age group.

Women should be assessed prenatally for evidence of varicella immunity. On completion or termination of their pregnancies, women who do not have evidence of varicella immunity should receive the first dose of varicella vaccine before discharge from the health care facility. The second dose should be administered 4 to 8 weeks later at the postpartum or other health care visit. To ensure administration of varicella vaccine, standing orders are recommended for health care settings where completion or termination of pregnancy occurs.

Postexposure prophylaxis. Data from the United States and Japan in a variety of settings indicate that varicella vaccine is 70% to 100% effective in preventing illness or modifying the severity of illness if it is used within 3 days and possibly up to 5 days after exposure.^{573,672} The ACIP recommends administration of varicella vaccine to people without evidence of immunity 12 months or older, including adults, as soon as possible within 72 hours and possibly up to 120 hours after varicella exposure.⁴⁵¹ Varicella vaccine may prevent or modify disease and should be considered in these circumstances if there are no contraindications to its use. A second dose should be given at the age-appropriate interval after the first dose. Physicians should advise parents and their children that the vaccine may not protect against disease in all cases because some children might have been exposed at the same time as the index case. However, if exposure to varicella does not cause infection, post-exposure immunization with varicella vaccine will result in protection against subsequent exposure. There is no evidence that administration of varicella vaccine during the presymptomatic or prodromal stage of illness increases the risk of vaccine-associated adverse events or more severe natural disease.

In 2006, the ACIP approved a revised definition for evidence of immunity to varicella.⁴⁵¹ Revised criteria for evidence of immunity to varicella include any of the following:

- Documentation of age-appropriate vaccination
- Preschool-aged children 12 months or older: one dose
- School-age children, adolescents, and adults: two doses
- Laboratory evidence of immunity or laboratory confirmation of disease
- Birth in the United States before 1980
- Diagnosis of varicella or verification of history of varicella disease by a health care provider
- History of herpes zoster based on health care provider diagnosis

Precautions and Contraindications

Varicella-containing vaccines are contraindicated for pregnancy, severe febrile illness, known history of anaphylactic reaction to vaccine components, and immunodeficiency states (i.e., malignancy, primary immunodeficiency disease, immunosuppressive or corticosteroid therapy, and radiation therapy).^{26,23,49,155,450,451}

Varicella vaccine should not be administered to people who have had an anaphylactic-type reaction to any component of the vaccine, including gelatin and neomycin. Most people with allergy to neomycin have resulting contact dermatitis, a reaction that is not a contraindication to immunization. Monovalent varicella vaccine does not contain preservatives or egg protein, and although the measles and mumps vaccines included in MMRV vaccine are produced in chick embryo culture, the amounts of egg cross-reacting proteins are not significant. Children with egg allergy routinely can be given MMRV without previous skin testing.

Varicella vaccine should not be administered routinely to children who have congenital or acquired T-lymphocyte immunodeficiency, including those with leukemia, lymphoma, and other malignant neoplasms affecting the bone marrow or lymphatic systems, and children receiving long-term immunosuppressive therapy. An exception includes certain children infected with HIV (discussed later). Children with impaired humoral immunity can be immunized.

Immunodeficiency should be excluded before immunization of children with a family history of hereditary immunodeficiency. An immunodeficient or HIV-seropositive household family member does not contraindicate vaccine use in other family members.

In people with possible altered immunity, immunization against chickenpox should use only monovalent varicella vaccine. The Oka vaccine strain remains susceptible to acyclovir. If a high-risk patient develops vaccine-related varicella, acyclovir should be used as treatment.

Before routine immunization of healthy children against varicella was instituted in the United States in 1995, many young children with leukemia were susceptible to chickenpox. Considering the variation in intensity of chemotherapy regimens and the decreasing incidence of varicella in the United States, these high-risk children should not be immunized routinely. Immunization of susceptible leukemic children without evidence of immunity in remission should be undertaken only with expert guidance and with availability of antiviral therapy in case complications occur.

Live virus vaccines usually are withheld for an interval of at least 3 months after immunosuppressive cancer chemotherapy has been discontinued. However, the interval until immune reconstruction varies with the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors. It often is not possible to make a definitive recommendation for an interval after cessation of immunosuppressive therapy when live virus vaccines can be administered safely and effectively.

Screening for HIV infection is not indicated before routine VZV immunization. Varicella vaccine should be considered for nonimmune HIV-infected children with a CD4⁺ T-lymphocyte percentage of 15% or greater, especially if they are receiving antiretroviral therapy.⁴⁸² Eligible children should receive two doses of monovalent varicella vaccine with a 3-month interval between doses and return for evaluation if they experience a postimmunization varicella-like rash. Hundreds of HIV-infected children have been safely immunized in the United States, and the vaccine is tolerated much as it is in healthy immunized children. Varicella vaccine has protected these children against varicella and herpes zoster by preventing infection with wild-type VZV.

Varicella vaccine should not be administered to people who are receiving high doses of systemic corticosteroids (i.e., 2 mg/kg per day or more of prednisone or its equivalent or 20 mg/day of prednisone or its equivalent) for 14 days or more. The recommended interval between discontinuation of corticosteroid therapy and immunization with varicella vaccine is at least 1 month. Varicella vaccine may be administered to people receiving inhaled, nasal, and topical corticosteroids. The results of one small study indicate that two doses of the varicella vaccine in 29 children with nephrotic syndrome between 12 months and 18 years of age usually were well tolerated and immunogenic, including children receiving low-dose, alternate-day prednisone.

Household contacts of immunocompromised people should be immunized if they have no evidence of immunity to decrease the likelihood that wild-type VZV will be introduced in the household. Transmission of vaccine-strain VZV from healthy people has been documented in seven instances, resulting in eight secondary cases. Even in families with immunocompromised people, including people with HIV infection, no precautions are needed after immunization of healthy children in whom a rash does not develop. Immunized people in whom a rash develops should avoid direct contact with immunocompromised hosts without evidence of immunity for the duration of the rash.

Receipt of antibody-containing blood products (i.e., whole blood, plasma, or parenteral immune globulin) may interfere with seroconversion to varicella vaccine. The length of time that such passively acquired antibody persists depends on the concentration and quantity of the blood product received⁴⁰⁸ (see Table 245.11).

Although no direct evidence demonstrates that varicella vaccine is harmful to a pregnant woman or her fetus, the vaccine should not be administered to women known to be pregnant or considering becoming pregnant within the month because of the theoretical risk of fetal infection associated with a live virus vaccine. Vaccinated women should avoid conception for 1 month after receiving vaccination.

The manufacturer established a Varicella Vaccination in Pregnancy Registry to monitor the maternal-fetal outcomes of pregnant women inadvertently given varicella vaccine. The registry was closed in October 2013 because the low rate of exposure of varicella-susceptible women of childbearing age to VZV-containing vaccines, in addition to the rarity of the outcome, contributed to the low feasibility of the registry providing more robust data on the risk of congenital varicella syndrome within a reasonable timeframe.⁴⁵³ A summary of 18 years of registry data found no cases of congenital varicella syndrome and no increased prevalence for other birth defects after exposure to VZV-containing vaccines during pregnancy. However, the number of exposures was insufficient to exclude a very low risk of congenital varicella syndrome in varicella-susceptible women exposed during the high-risk period.⁶⁸⁹

A study of nursing mothers and their infants showed no evidence of excretion of vaccine strain in human milk or of transmission to infants who are breastfeeding. Varicella vaccine should be administered to nursing mothers who lack evidence of immunity.

Reye syndrome has occurred in children infected with varicella who receive salicylates. Whether varicella vaccine may induce Reye syndrome is not known, but the vaccine manufacturer recommends that salicylates not be given within at least 6 weeks after administration of varicella vaccine.

Diseases for Which Combination Vaccines Are Available

Many new and improved vaccines have been introduced over the past 20 years. Incorporation of these vaccines into already complex childhood immunization schedules has posed a challenge. In the 2016 Recommended

Immunization Schedule in the United States, a minimum of 22 separate injections are needed to immunize a child from birth to 2 years of age.^{210,560} At some visits, the administration of three to five separate injections can be indicated.

Combination vaccines represent one solution to the problem of increased numbers of injections. These vaccines incorporate into a single product antigens that prevent several diseases. Combinations licensed in recent years in the United States are shown in Table 245.18.

Licensed combination vaccines can be used when any components of the combination are indicated and its other components are not contraindicated and if licensed by the FDA for that dose in the series.⁴⁰⁸ Use of combination vaccines can reduce the number of injections patients receive and alleviate parental concerns about the number of injections. Potential advantages of combination vaccines include improved vaccine coverage rates, timely vaccination coverage for children who need catch-up vaccination, reduced shipping and stocking costs, reduced costs for extra health care visits necessitated by deferral of vaccination, and facilitation of adding new vaccines into vaccination programs.

Potential disadvantages of combination vaccines include adverse events that may occur more frequently after administration of a combination vaccine compared with administration of separate antigens at the same visit, such as those that occur with the MMRV vaccine and combination DTaP-hepatitis B-IPV vaccine^{450,637}; confusion and uncertainty about selection of vaccine combinations and schedules for subsequent doses, especially when vaccinations are given by multiple providers who might be using different products; reduced immunogenicity of one or more components²³⁸; extra doses of certain antigens in the fixed product (e.g., a provider who uses DTaP-hepatitis B-IPV vaccine will give an extra dose of hepatitis B component); and a shorter shelf-life than the individual component vaccines. The economic impact of the use of combination vaccines is unclear because combination products have the potential for increased or decreased costs compared with single-antigen component vaccines.

The minimum age for administration of a combination vaccine is the oldest minimum age for any of the individual components; the minimum interval between doses is equal to the greatest minimum interval of any of the individual components. When patients have received the recommended immunizations for some of the components in a combination vaccine, administering the extra antigens in the combination vaccine is permissible if they are not contraindicated and doing so will reduce the number of injections required. However, excessive doses of toxoid vaccines (i.e., diphtheria and tetanus) can result in extensive local reactions.

Only combination vaccines licensed by the FDA should be used. Separate vaccines should not be combined into the same syringe for administration together unless mixing is indicated for the patient's age and is explicitly specified on the FDA-approved product label inserts. Only one combination vaccine (i.e., DTaP-IPV/Hib vaccine [Pentacel])

TABLE 245.18 Combination Vaccines Licensed in the United States^a

Vaccine ^b	Trade Name (year licensed)	Age Range	Routinely Recommended Ages
DTaP-HepB-IPV	Pediarix (2002)	6 wk–6 y	Three-dose series at 2, 4 and 6 mo
DTaP-IPV/Hib	Pentacel (2008)	6 wk–4 y	Four-dose series at 2, 4, 6, and 15–18 mo
DTaP-IPV	Kinrix (2008)	4–6 y	Fifth dose of DTaP and fourth dose of IPV
DTaP-IPV	Quadracel (2015)	4–6 y	Fifth dose of DTaP and fourth or fifth dose of IPV
HepA-HepB	Twinrix (2001)	≥18 y	Three doses on a schedule of 0, 1, and 6 mo
Hib-MenCY	MenHibrix (2012)	2–23 mo	Four-dose series at 2, 4, 6, and 15–18 mo
MMRV	ProQuad (2005)	12 mo–12 y	Two doses, the first at 12–15 mo, the second at 4–6 y

^aExcludes measles-mumps-rubella (MMR), DTaP, Tdap, Td, and IPV vaccines, for which individual components are not available. DTaP/Hib (TriHibit) and Hib/HepB (Comvax) are no longer manufactured.

^bA hyphen (-) between vaccine products indicates that products are supplied in their final form by the manufacturer and do not require mixing or reconstitution by the user. A slash (/) indicates that the products must be mixed or reconstituted by the user.

DTaP, Diphtheria-tetanus-acellular pertussis; HepA, hepatitis A; HepB, hepatitis B; Hib, *Haemophilus influenzae* type b; IPV, inactivated poliovirus; MenCY, meningococcal group CY; MMRV, measles-mumps-rubella-varicella.

Modified from American Academy of Pediatrics. Combination vaccines. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:36–7.

contains separate antigen components for which FDA approves mixing by the user. The safety, immunogenicity, and efficacy of unlicensed combinations are unknown.

Licensure of a combination vaccine by the FDA is based on studies demonstrating that the product's immunogenicity (or efficacy) and safety are comparable or equivalent to monovalent or combination products licensed previously. FDA licensure also indicates that a combination vaccine may be used interchangeably with monovalent formulations and other combination products with similar component antigens produced by the same manufacturer to continue the vaccination series. For example, DTaP, DTaP/Hib, and future DTaP vaccines that contain similar acellular pertussis antigens from the same manufacturer may be used interchangeably if licensed and indicated for the patient's age.¹⁵²

Licensure of a vaccine by the FDA does not necessarily indicate that the vaccine is interchangeable with products from other manufacturers. Data are readily available for diseases with known serologic correlates of protective immunity. For diseases without surrogate laboratory markers, prelicensure field vaccine efficacy (phase III) trials or postlicensure surveillance usually are required to determine protection.⁴⁷⁸ The ACIP prefers that doses of vaccine in a series come from the same manufacturer; however, if this is not possible or if the manufacturer of doses of vaccine given previously is unknown, providers should administer the vaccine that they have available.

VACCINES WITH SELECTIVE INDICATIONS FOR CHILDREN AND ADOLESCENTS

Bacille Calmette-Guérin Vaccine

Effective control of tuberculosis in the United States has been achieved by the early identification and treatment of cases, followed by surveillance of household and other close contacts and institution of appropriate preventive measures for those at high risk for disease development. In the United States, the mainstay of preventive therapy is isoniazid chemoprophylaxis, which is used in asymptotically infected people to prevent the progression of infection to disease. In selected instances, however, the potential for acquiring disease, poor compliance by contacts instructed to take chemoprophylaxis, or failure of chemoprophylaxis may justify the use of immunoprophylaxis.¹²⁷

Bacille Calmette-Guérin (BCG) is not usually recommended for immunoprophylaxis in the United States because of the low risk of infection with *Mycobacterium tuberculosis*, the unpredictable effectiveness of the vaccine against adult pulmonary tuberculosis, and the vaccine's potential interference with tuberculin skin test reactivity. Elsewhere in the world, BCG vaccine is used in more than 100 countries and is recommended routinely at birth by the WHO⁶⁹⁶ (http://www.who.int/immunization/policy/Immunization_routine_table2.pdf?ua=1). Of primary concern to pediatricians is the risk to an infant born to a mother with tuberculosis or living within a household with other identified individuals with tuberculosis.⁴⁸

Preparations

BCG is the only approved vaccine against tuberculosis. BCG is a live attenuated strain derived from *Mycobacterium bovis*. All currently available BCG vaccines are derived from the original strain at the Pasteur Institute in Paris, but they have been propagated by different methods in many laboratories and therefore vary in their immunogenic and reactogenic properties. BCG (Merck) is the only vaccine licensed in the United States. Comparative evaluations of this preparation and other BCG vaccines have not been performed.

BCG is administered only percutaneously using a sterile multiple-puncture device. The standard dose of BCG vaccine is 0.2 to 0.3 mL of reconstituted lyophilized BCG. At least 10 new potential vaccines to prevent tuberculosis are in clinical development.²⁷⁴ Nevertheless, BCG will remain in use in the foreseeable future and may continue to be used as a prime vaccine in a prime-boost immunization schedule in conjunction with new tuberculosis vaccines.³⁸³ BCG preparations instilled in the treatment of bladder cancer are not intended to be used as vaccines.¹²⁷

Immunogenicity and Efficacy

BCG is used primarily in young infants in an attempt to prevent disseminated and other life-threatening manifestations of *M. tuberculosis* disease. However, BCG does not prevent infection with *M. tuberculosis*. The efficacy of different BCG vaccines seems to vary broadly. Two meta-analyses of published clinical trials and case-control studies concerning the efficacy of BCG vaccines concluded that BCG has relatively high protective efficacy (approximately 80%) against meningeal and miliary tuberculosis in children.^{207,562} The protective efficacy against pulmonary tuberculosis, however, differed significantly among the studies, precluding a specific conclusion. Protection afforded by BCG in one meta-analysis was estimated to be 50%.²⁰⁷

Adverse Events

Four billion doses of BCG have been administered with a proven safety record.³⁸³ BCG vaccination usually results in scarring at the site of injection. However, the vaccine has been associated uncommonly (1–2% of vaccinations) with local adverse reactions such as subcutaneous abscess and lymphadenopathy, which are not usually serious. Osteitis affecting the epiphyses of long bones is a rare complication that develops in 1 of 1 million vaccinees and may occur as long as several years after receiving BCG immunization. The rate may be higher among neonates. Disseminated fatal disease occurs rarely (0.1–1 case/1 million vaccinees), primarily in people with severely impaired immune systems.^{127,409,438,621}

Antituberculosis therapy, except for pyrazinamide, is recommended to treat osteitis and disseminated disease caused by BCG. Some experts also recommend treatment of chronic suppurative lymphadenitis caused by BCG. People with complications caused by BCG should be referred to a tuberculosis expert for management.

Indications

In the United States, administration of BCG should be considered only in limited and select circumstances, such as unavoidable risk of exposure to *M. tuberculosis* and failure or unfeasibility of other methods of control of tuberculosis. The ACIP and AAP have published recommendations for the use of BCG to control tuberculosis in children.^{33,169} Healthy infants from birth to 2 months of age may be given BCG without tuberculin skin testing; thereafter, BCG is given only to children with a negative tuberculin skin test result. BCG immunization should be considered for infants and children who are not infected with HIV in the following circumstances:

- The child is exposed continually to a person or people with contagious pulmonary tuberculosis resistant to isoniazid and rifampin, and the child cannot be removed from this exposure.
- The child is exposed continually to a person or people with untreated or ineffectively treated contagious pulmonary tuberculosis, and the child cannot be removed from the exposure or given antituberculosis therapy.

Careful assessment of the potential risks and benefits of BCG vaccine and consultation with personnel in local area control programs for tuberculosis are strongly recommended before the use of BCG. When BCG vaccine is given, care should be taken to observe the precautions and directions for administration on the product label. Other childhood vaccines can be administered concurrently with BCG.

Skin Test Reactivity

Recipients of BCG should have repeat tuberculin skin tests 2 to 3 months after immunization to establish that tuberculin cellular reactivity has developed. Failure to react dictates the need for repeat BCG vaccination followed by repeat tuberculin testing.¹²⁷ The tuberculin reaction to the BCG vaccine available in the United States usually results in 7 to 15 mm of induration after vaccination and diminishes gradually during subsequent years. Without revaccination or repeated exposure to *M. tuberculosis*, reactivity usually disappears within 10 years.¹²⁷ The size of the area of induration may be correlated with the number of doses of BCG.³⁵⁷ However, tuberculin skin test sensitivity does not correlate with BCG efficacy.³³⁷ In BCG recipients, differentiating between a tuberculin reaction representing acquired tuberculous infection and persistent postvaccination reactivity is difficult.

Because the degree and duration of protection against tuberculous disease afforded by BCG are uncertain, a positive tuberculin reaction may be indicative of disease. BCG recipients with a positive tuberculin skin test result should be carefully evaluated with risk assessment, radiography, and other diagnostic tests, including an interferon- γ release assay (IGRA), which does not produce cross-reactions after sensitization by BCG.⁴⁶⁷

Precautions and Contraindications

BCG vaccine should not be administered to individuals with burns, skin infections, and certain primary or secondary immunodeficiencies, including HIV infection, because of the risk of disseminated BCG disease. The use of BCG vaccine also is contraindicated in people receiving immunosuppressive medications, including high-dose corticosteroids.

In the United States, where the risk of acquiring tuberculosis is low, BCG vaccine should not be administered to children with known or suspected asymptomatic HIV infection.^{127,510} However, in countries where the risk of contracting tuberculosis is high and HIV surveillance of pregnant women and infants is limited, the WHO has recommended that asymptomatic HIV-infected children receive BCG vaccine at birth or shortly thereafter.^{696,695} However, the WHO recommends that BCG should not be administered to infants known to be infected with HIV even in resource-poor regions because the risk of disseminated BCG in these infants is significantly high, approaching 1%.^{698,699} Although no harmful effects of BCG vaccine on the fetus have been documented, women should avoid receiving vaccination during pregnancy.

Cholera Vaccine

The global burden of cholera is difficult to estimate due to underreporting, but experts place the annual number of cases at 2.9 million with 95,000 deaths.⁸ In 2009, 45 countries reported 221,226 cholera cases with 4946 deaths to the WHO, with 98% of cases and 99% of deaths reported from Africa.⁵⁶⁶ In 2010, an outbreak of cholera occurred in Haiti with more than one-half million cases and more than 7000 confirmed deaths. It was the first epidemic in the Western Hemisphere since the 1991 epidemic in Peru.⁶ After it emerged in Haiti, cholera spread to other countries, including the Dominican Republic and Cuba.

From 2001 through 2013, 123 confirmed cases of cholera in the United States were acquired abroad; of these, 63 were associated with the epidemic in Hispaniola.⁴³⁶ Most cases of disease have occurred in travelers to cholera-affected areas or people who have eaten contaminated food brought or imported from these areas.¹²² Although cholera remains a significant public health concern in African, Asian, and South American countries, even in these countries the risk to US travelers is low. People following the usual tourist itinerary that use standard accommodations in countries reporting cholera are at very low risk for infection.⁵⁶⁶

Preparations

There are two major types of oral vaccines against cholera: killed whole cell-based and genetically attenuated live vaccines.³⁴⁵ A single cholera vaccine CVD 103-HgR (Vaxchora; PaxVax, Redwood City, CA) is available in the United States. This vaccine is an attenuated live oral genetically modified *V. cholerae* O1 strain (CVD 103-HgR) and was licensed by FDA in 2016 for United States travelers 18 to 64 years of age visiting endemic countries.

Two other vaccines are prequalified by WHO and are available in many countries outside the United States: WC/rBS (Dukoral; Crucell, the Netherlands) and Modified WC-only (Shanchol; Shantha Biotechnics, Medchal, Hyderabad, India). The WC/rBS vaccine is a whole, killed cell-based vaccine that contains *Vibrio cholerae* O1 with purified recombinant B subunit of cholera toxin. The modified WC-only vaccine is also a whole, killed cell-based vaccine but lacks the B subunit. The WC-only vaccine was originally manufactured by the government of Vietnam. Although inexpensive to produce, it did not elicit antitoxic immunity. In 2007, the WC-only vaccine was modified with international efforts to create a low-cost vaccine that is produced in India.^{572,599}

Immunogenicity and Efficacy

In a randomized, placebo-controlled, double-blind trial of the CVD 103-HgR vaccine with an oral cholera challenge in 197 health human

volunteers, vaccine efficacy was found to be 90% at 10 days and 80% 3 months after a single vaccine dose.¹⁸⁴ Although the CVD 103-HgR vaccine provides protective vibriocidal antibodies in 90% of vaccinees, it is specific to *V. cholerae* serogroup O1 and does not confer protection to O139 or other non-O1 serogroups.¹⁸⁴ CVD 103-HgR vaccines have the benefit of being efficacious with a onetime dose instead of the two spaced doses required of the killed, whole cell vaccines.

WC/rBS vaccine confers protection specific to *V. cholerae* serogroup O1.³⁴⁵ Immunization does not protect against *V. cholerae* serogroup O139 or other species of *Vibrio*. Field trials in Bangladesh, Peru, and Sweden have shown that the WC/rBS vaccine confers 85% to 90% protection for 6 months in all age groups after administration of two doses 1 week apart. In Bangladesh, protection declined rapidly after 6 months in young children, but it was still approximately 60% effective in older children and adults after 2 years. Because of the limited duration of protection, the WC/rBS vaccine is not recommended to be used in children younger than 2 years.

The modified killed, whole cell-only vaccine had been studied in several trials and found to be safe and highly effective, with seroconversion rates of vibriocidal antibodies ranging from 53% to 91%.^{54,572,599,628} Limited data on the safety and immunogenicity of the modified whole-cell-based vaccine in children at least 1 year of age appear promising.⁵⁷²

Adverse Events

In clinical trials of the newly licensed CVD 103-HgR vaccine, there was no difference between placebo and vaccine recipients with respect to diarrhea, asthenia, headache, abdominal pain, anorexia, nausea and vomiting, or fever.¹⁸⁴

Millions of doses of WC/rBS vaccine have been supplied worldwide.³⁴⁵ According to manufacturer information from clinical trials and post-marketing surveillance, mild gastrointestinal symptoms (e.g., abdominal pain, cramping, diarrhea, nausea) are most commonly reported, occurring at a frequency of 0.1% to 1%. Serious adverse events, including a flulike syndrome, rash, arthralgia, and paresthesias, are rare, occurring in less than one of 10,000 doses distributed. In several RCTs, the modified, killed, whole cell-only vaccine also demonstrated a low frequency of mild symptoms and no major adverse events.^{54,572,628}

Indications

In June 2016, the ACIP voted to recommend cholera vaccine (CVD 103-HgR, Vaxchora) for adult (18–64 years old) travelers to an area of active toxigenic *V. cholerae* O1 transmission. Special consideration should be given for those at higher than average risk, such as health care professionals in endemic areas, aid workers in refugee camps, and those traveling to remote areas where cholera epidemics are occurring and access to medical care is limited. No country requires proof of cholera immunization as a condition for entry, and the WHO recommends against such a requirement. Some local authorities, however, may require immunization; to determine local requirements, travelers should consult the embassies of the countries to which they will be traveling.

Precautions and Contraindications

Oral cholera vaccine should not be administered to people with a hypersensitivity reaction to any of the vaccine components. Administration of oral cholera vaccine should be postponed for people with acute gastrointestinal illness or acute febrile illness.

Japanese Encephalitis Virus Vaccine

Japanese encephalitis (JE) virus, the most important cause of epidemic mosquito-borne arboviral encephalitis in Asia, has a wide clinical spectrum, ranging from asymptomatic infection to permanent neurologic sequelae associated with a high rate of disability (i.e., 709,000 disability-adjusted life-years), and a high case-fatality rate of 20% to 30% or even higher among children younger than 10 years. The annual incidence of JE among 3 billion people at risk in 24 countries in Southeast Asia and the Western Pacific is 1.8 case per 100,000 people despite the availability of effective vaccines in many regions.⁷⁰⁰

The JE virus is a zoonotic flavivirus that cannot be eliminated because its animal reservoirs are widespread. However, human infection could be controlled by universal human immunization in endemic areas. The

envelope glycoprotein of the JE virus contains the major epitopes that are targeted by neutralizing antibodies.

Historically, an inactivated mouse brain–derived vaccine (JE-VAX) controlled JE virus infection successfully among human populations in Japan, Korea, and Taiwan since 1968.⁵¹⁷ This vaccine is no longer available in the United States and is being phased out elsewhere because of greater reactogenicity, higher cost, and larger number of doses compared with the newer-generation vaccines.

Preparations

The 15 JE vaccines in use in Asia are classified in four categories: inactivated mouse brain–derived vaccines, inactivated Vero cell–derived vaccines, live attenuated vaccines, and live recombinant (chimeric) vaccines. In the United States, the inactivated Vero cell–derived, alum-adjuvanted vaccine, JE-VC (Ixiaro, Intercell Biomedical, United Kingdom, distributed by Novartis Vaccines and Diagnostics in the United States) is indicated for use in individuals 2 months and older.¹⁷⁷ It is derived from the attenuated SA 14-14-2 JEV strain.

The primary vaccination series for JE-VC is two intramuscular doses administered 28 days apart. The dose for children younger than 3 years is 0.25 mL, and 0.5 mL is given to children 3 years or older.¹⁷⁷ The vaccine does not contain stabilizers, antibiotics, or thimerosal and should be stored at 2°C to 8°C (35°F–46°F) and protected from light.

A primary hamster kidney cell–derived, live attenuated vaccine (CDJEVAX) has been used widely in China since 1988 and is used widely in Asia now. It is based on the SA 14-14-2 JEV strain. Primary immunization consists of a single 0.5-mL subcutaneous dose in children 8 months or older. It contains gelatin, human serum albumin, and other stabilizers.

A live attenuated, recombinant (chimeric) JE virus vaccine (IMOJEV, JE-CV, ChimeriVax-JE) was licensed in Australia in 2010 and is used widely in Asia. The premembrane and envelope coding sequences derived from the SA 14-14-2 JEV strain were engineered to replace the homologous sequences of the live attenuated yellow fever vaccine virus, which is used as a vector. This vaccine is propagated in Vero cells. Primary immunization is a single dose of 0.5 mL given subcutaneously at 9 months or older, and a booster dose is indicated for children.

Immunogenicity and Efficacy

The JE-VC vaccine was licensed in the United States on the basis of its ability to induce JE virus–neutralizing antibodies as a surrogate for protection and safety evaluations in approximately 5000 adults.⁵⁸⁷ The accepted immunologic surrogate of protection is a serum neutralizing antibody titer of at least 1:10 as determined by a 50% plaque reduction neutralization assay (PRNT₅₀) result.⁷⁰⁰

Vaccine effectiveness for the inactivated JE-VC vaccine is at least 93%, 80% to 99% for the live attenuated JE vaccines, and at least 90% for the live recombinant vaccines. Long-term immunogenicity data are limited. A booster vaccine is recommended 2 years after the primary series to induce a robust anamnestic response.⁷⁰⁰

Mass immunization campaigns with live attenuated and inactivated mouse brain–derived JE vaccines significantly reduce JE disease in a community. No data are available for the inactivated Vero cell–derived and live recombinant vaccines.

Adverse Reactions

The inactivated Vero cell–derived vaccines, live attenuated vaccines, and live recombinant vaccines all have acceptable safety profiles. The most common local reactions to JE-VC are rash, fever, headache, myalgia, and fatigue, but severe reactions occur in 1.6 of 100,000 administered doses,^{177,700} as described on the CDC website (<http://www.cdc.gov/vaccines/acip/recs/grade/je-child.html>). Severe adverse events include febrile convulsions, thrombocytopenic purpura, and encephalitis.²⁴⁷ The other vaccine preparations are associated with similar reactogenicity and tolerability as that of JE-VC.

Indications

The risk of JE for most travelers to Asia is low but varies on the basis of destination, duration, season, and activities. All travelers to countries with endemic JE should be informed of the risks of JE and use personal

protective measures (i.e., bed nets and mosquito repellants) to reduce the risk of mosquito bites. For some travelers who will be in high-risk settings, JE vaccine can further reduce the risk of infection. The CDC recommends JE vaccine for travelers who plan to spend a month or longer in areas with endemic infection during the JE virus transmission season.^{30,271} JE vaccine should be considered for shorter-term travelers if they plan to travel away from an urban area and have an itinerary or activities that increase the risk of JE virus exposure. Information on the location of JE virus transmission and detailed information on vaccine recommendations and adverse events can be obtained from the CDC website (<https://wwwnc.cdc.gov/travel>).

Primary immunization with JE-VC should be completed at least 1 week before potential exposure to JE virus. If the primary series was administered more than 1 year earlier, a booster dose is recommended for individuals older than 16 years before potential reexposure.²⁴⁸ Data on the response to a booster dose administered more than 2 years after the primary series and the need for and timing of additional booster doses are not available. There is no information about the utility of booster doses for children. The sparse available data suggest that the different JE vaccines are interchangeable without causing adverse reactions or compromising immunogenicity.

Precautions and Contraindications

A severe allergic reaction after a previous dose of JE-VC is a contraindication to administration of subsequent doses.²⁷¹ JE-VC contains protamine sulfate, a compound known to cause hypersensitivity reactions in some people.

Practitioners should use caution when considering the use of JE vaccine in pregnant women. Vaccination with JE vaccines usually should be deferred because of a theoretical risk to the developing fetus. However, pregnant women who must travel to an area in which the risk of JE exposure is high should be vaccinated with an inactivated JE vaccine if the benefits outweigh the risks of vaccination for the mother and developing fetus.

Breastfeeding is not a contraindication to vaccination with inactivated JE vaccine. However, whether JE-VC is excreted in human milk is not known. Because many drugs are excreted in human milk, practitioners should use caution when considering the use of inactivated JE vaccine in breastfeeding women.

No data exist on the use of JE-VC in immunocompromised people or patients receiving immunosuppressive therapies.

Rabies Vaccine

Rabies is a viral zoonosis transmitted in saliva and other tissue of infected mammals. The virus enters the central nervous system of the host and causes an acute, progressive encephalomyelitis that is almost universally fatal. Postexposure prophylaxis is possible because of the long incubation period, usually weeks to months, of this infection. The time of incubation correlates with the length of the axon along which the virus migrates to eventually infect the central nervous system. Children are at particular risk of exposure to rabies from an infected dog, cat, or other animal because they are less likely to take aversive measures if attacked and are more likely to sustain an injury to the head or neck. Accordingly, children are likely to have shorter incubation periods especially with an exposure injury on the head or neck.

In this century, the number of human deaths in the United States attributed to rabies has declined from 100 or more each year to an average of 2 or 3 each year. Two programs have been responsible for this decline. First, animal control and vaccination programs begun in the 1940s and oral rabies vaccination programs in the 2000s have eliminated domestic dogs as reservoirs of rabies in the United States. Second, effective human rabies vaccines and immunoglobulins have been developed.

Wild animals are the most important source of infection for humans and domestic animals. Insectivorous bats carrying variants of the rabies virus have been responsible for most human cases of rabies in the continental United States in recent years. Transmission has occurred from minor and unrecognized bites from infected bats. Wild carnivores, especially raccoons, skunks, and foxes, are the terrestrial animals most often infected with rabies. Wildlife rabies occurs throughout the

continental United States; only Hawaii remains consistently free of rabies. Domestic animals, including dogs, cats, and ferrets, can be infected, with three times as many reports of rabies annually in cats compared with dogs.

Human exposure to rabies from a domestic animal in the United States is a rare occurrence. In most other countries (e.g., Asia, Africa, and Latin America), dogs remain the most important potential source of infection. International travelers in areas where canine rabies is endemic are at increased risk for exposure to rabies.

Rabies was diagnosed in a total of 37 people in the United States since 2003.⁴⁸⁵ Seventy percent of them acquired the disease in the United States or Puerto Rico. Organ or tissue transplantation was identified as the source of infection for 19% of individuals. Bats were implicated as the source of infection in 65%, with a bat bite reported in seven cases bat contact without a reported bite in six cases and a rabies virus associated with bats without a known exposure identified in four cases. Thirty percent of human rabies deaths reported to the CDC since 2003 appear to have been related to rabid animals outside the United States.

Preparations

Two rabies vaccines are available for preexposure and postexposure prophylaxis in the United States: human diploid cell vaccine (HDCV) and purified chicken embryo cell (PCEC). Both vaccines are licensed for intramuscular administration. HDCV (Imovax Rabies, Sanofi Pasteur) is derived from the Pitman-Moore strain grown in human diploid cell culture. PCEC (RabAvert, Chiron Corporation-Novartis) is prepared from the fixed rabies virus strain Flury LEP grown in primary culture of chicken fibroblasts. The HDCV and PCEC vaccines each contain the WHO-recommended standard of at least 2.5 IU of rabies virus antigen per 1.0-mL intramuscular dose. Although not licensed for use in the United States, two intradermal rabies vaccines are recommended by the WHO and used in countries where the two tissue culture vaccines (i.e., HDCV and PCEC) are prohibitively expensive.¹³²

Immunogenicity and Efficacy

Viral neutralizing antibodies are produced within 7 to 10 days, and protective immunity usually persists for 2 years or longer. Although a definitive protective titer has not been identified, the WHO and CDC adhere to working guidelines for an acceptable response to immunization.¹¹⁸ The CDC specifies complete viral neutralization at a 1:5 or greater titer by the rapid fluorescent-focus inhibition test as acceptable; the WHO specifies 0.5 IU/mL or more as acceptable.

Given the essentially universal fatal prognosis of infection after symptoms develop, no randomized, placebo-controlled human trials have documented the efficacy of vaccine for preexposure or postexposure prophylaxis. However, substantial field experience and direct evidence from controlled animal studies demonstrate a protective effect. The paucity of human cases attests to the efficacy of postexposure prophylaxis with the currently recommended vaccine and immune globulin preparations.

Rabies has not been reported in the United States in any patient who received the recommended postexposure measures. Cases of human rabies occurring after postexposure prophylaxis have resulted from failure to adhere to established guidelines, such as those of the CDC or the WHO.^{117,250,272,598,673}

Adverse Events

Reactions occurring after administration of HDCV or PCEC vaccine are less serious and less common than those associated with the previously available vaccines.¹³² Local reactions at the injection site occur in 30% to 74% of injections, and mild systemic reactions such as fever, headache, nausea, abdominal pain, muscle aches, and dizziness occur in 5% to 40% of vaccine recipients. In one report, approximately 6% of people had an immune complex–like reaction 2 to 21 days after receipt of the booster dose of HDCV.¹⁰⁸ This systemic hypersensitivity reaction occurred less frequently in people receiving primary vaccination. The reactions have been associated with the presence of β -propiolactone–altered human albumin in HDCV and the development of IgE antibodies to this allergen.²⁷³

Indications and Precautions

When used as indicated, both types of rabies vaccine are considered equally safe and effective for preexposure and postexposure prophylaxis as described in the ACIP recommendations.^{448,570} Usually, an immunization series is initiated and completed with one vaccine product. No clinical studies have been conducted that documented a change in efficacy or the frequency of adverse reactions when the series is completed with a second vaccine product. Ideally, an immunization series should be completed with the same product unless serious allergic reactions occur. Corticosteroids, immunosuppressive conditions, and concurrent administration of antimalarial agents can interfere with the adequate development of an active immune response. Postvaccination titers should be checked in these circumstances or if a significant interruption in vaccine schedule has occurred, especially in the context of a more significant exposure, and in consultation with local public health authorities.

For adults, rabies vaccination always should be administered in the deltoid area. For children, the anterolateral aspect of the thigh also is acceptable. The gluteal area never should be used for HDCV or PCEC injections because administration of HDCV in this area results in lower neutralizing antibody titers and decreased immunogenicity.²⁷²

Postexposure prophylaxis. The essential components of rabies postexposure prophylaxis are wound treatment and, for previously unvaccinated people, concurrent administration of human rabies immune globulin (HRIG) and vaccine (Table 245.19).^{448,570} The combination of active and passive immunization is indicated for the treatment of all bite and all non-bite exposures inflicted by animals suspected or proven to be rabid. Recommendations for the management of people with possible exposure to rabies include giving meticulous attention to thorough cleansing of the wound with soap and water. The decision to give rabies immunoprophylaxis depends on the circumstances precipitating the exposure, the species and condition of the animal inflicting the wound, and the prevalence of rabies in local animal populations. Bite and nonbite exposures, including scratches, abrasions, open wounds, and mucous membranes contaminated with saliva, are considered significant. Because the need for preventive measures is based on these specific circumstances, the local department of health should be consulted promptly concerning the necessity for initiating postexposure prophylaxis.

When possible, the brains of wild animals (i.e., skunks, foxes, coyotes, raccoons, and bats), stray dogs or cats, or symptomatic animals implicated in an exposure should be examined in certified laboratories for evidence of rabies. Immunization always should be initiated promptly and discontinued only if laboratory results are negative. Individuals exposed to healthy dogs or cats that are available for observation do not require immediate prophylactic treatment. Implicated healthy domestic dogs or cats should be quarantined and observed for at least 10 days. If symptoms develop that suggest rabies, the exposed individual should begin postexposure prophylaxis, and the brain of the animal should be examined. An unknown or unavailable animal must be regarded as potentially rabid.

Studies conducted in the United States by the CDC have documented that a regimen of one dose of HRIG and five doses of rabies vaccine (1.0 mL for each dose) given on days 0, 3, 7, 14 and 28 was safe and induced an excellent antibody response in all recipients.⁴⁴⁸ In March 2010, the ACIP changed recommendations to one dose of HRIG with four doses of rabies vaccine (1.0 mL for each dose) given on days 0, 3, 7, and 14. The number of doses recommended for people with altered immunocompetence has not changed; they should be administered a five-dose vaccination regimen (days 0, 3, 7, 14, and 28) along with one dose of HRIG.⁵⁷⁰ If anatomically feasible, the full dose of HRIG (20 IU/kg) should be infiltrated thoroughly in the area around and into the wounds. Any remaining volume should be injected intramuscularly at a site distant from that of vaccine administration. The dose of HRIG should not exceed that recommended and should not be given beyond the seventh day because HRIG can partially suppress active antibody production.

People previously fully vaccinated do not require HRIG and should receive only vaccine (two doses 3 days apart) because an amnestic response will occur after the administration of a booster regardless of

TABLE 245.19 Rabies Postexposure Prophylaxis for Individuals Not Previously Immunized

Animal Type	Evaluation and Disposition of the Animal	Postexposure Prophylaxis Recommendations
Wild		
Skunks, raccoons, foxes, and most other carnivores; bats	Regard as rabid unless animal proven negative by laboratory tests ^a	Consider immediate vaccination and if not previously vaccinated, use rabies immune globulin
Domestic		
Dogs, cats, and ferrets	Healthy and available for 10 days observation Rabid or suspected rabid Escaped (unknown)	Persons should not begin prophylaxis unless animal develops clinical signs of rabies ^b Immediately vaccinate Consult public health officials
Other		
Livestock, small rodents, large rodents (woodchucks and beavers), lagomorphs (rabbits and hares), and other mammals	Consider individually	Consult public health officials Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other small rodents, rabbits, and hares rarely require antirabies prophylaxis

^aThe animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results of the animal are negative.

^bDuring the 10-day observation period, begin postexposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.

Modified from Manning SE, Rupprecht CE, Fishbein D, et al. Human rabies prevention—United States, 2008: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep*. 2008;57(RR-3):1–28.

the antibody titer.⁴⁴⁸ Serum for antibody testing should be obtained from people whose prophylaxis history or immune status is uncertain, and the course of postexposure active and passive immunoprophylaxis as described for nonimmune individuals should be initiated immediately. If serologic testing demonstrates adequate anti-rabies antibody, post-exposure prophylaxis can be discontinued.

Once initiated, rabies prophylaxis should not be interrupted or discontinued because of local or mild systemic adverse reactions to rabies vaccine. Usually, the reactions can be successfully managed with antiinflammatory and antipyretic agents such as ibuprofen or acetaminophen. When a person with a history of serious hypersensitivity to rabies vaccine must be revaccinated, antihistamines can be administered. Epinephrine should be readily available to counteract any anaphylactic reactions, and the person should be observed carefully immediately after receiving vaccination.

Preexposure prophylaxis. Active immunization should be considered for high-risk groups (i.e., veterinarians, animal handlers and control officers, selected laboratory workers, people visiting countries where rabies is hyperendemic, and people whose pursuits may involve frequent contact with rabid animals, such as spelunkers). People whose risk of exposure is less but whose access to immediate competent medical care is restricted also should be considered for preexposure prophylaxis.

The primary series consists of three doses (1.0 mL/dose) administered on days 0, 7, and 21 or 28, given intramuscularly in the deltoid area. The three-dose series provides long-term protective immunity, and routine serologic testing for rabies antibody after primary immunization is not necessary. For individuals who may be immunosuppressed, measurement of anti-rabies antibodies should be performed. In the case of continued or frequent exposure, serum samples should be tested every 2 years and a booster dose of rabies vaccine provided when the antibody titer falls below the minimum accepted level.⁴⁴⁸

Precautions and Contraindications

Because of the potential consequences of inadequately treated rabies exposure and because no indication exists that fetal abnormalities have been associated with rabies vaccination, pregnancy is not considered a contraindication to postexposure prophylaxis.⁴⁴⁸ If the risk of exposure to rabies is substantial, preexposure prophylaxis also can be indicated during pregnancy.

People who have a history of serious hypersensitivity to rabies vaccine should be revaccinated with caution. Although serious systemic, anaphylactic, or neuromuscular reactions are rare events during and after the administration of rabies vaccines, the reactions pose a serious dilemma for the patient and the attending physician. A patient's risk

of acquiring rabies must be carefully considered before deciding to discontinue vaccination. Advice and assistance on the management of serious adverse reactions for people receiving rabies vaccines may be sought from the state health department or the CDC.

Typhoid Vaccine

Typhoid fever, an acute, life-threatening febrile illness caused by the bacterium *Salmonella enterica* serovar *typhi* (*S. typhi*), remains a serious public health problem throughout the developing world. Although disease prevalence varies greatly depending on the specific population studied, current global estimates suggest that 27 million cases of typhoid and 270,000 deaths occur annually.⁹⁷ In the United States and much of the developed world, typhoid fever has virtually disappeared.⁹⁷ Approximately 400 cases of typhoid fever, mostly among travelers, are reported to the CDC each year. Most reported cases in the United States are acquired during travel to developing countries.³⁷⁴ The primary indication for typhoid vaccination in the United States is international travel to an endemic area.³⁷³ In developing countries without safe water and sanitation, mass immunization is a potentially effective strategy to limit the severity and impact of typhoid fever.³

The changing epidemiology of typhoid fever underscores the importance of vaccination of international travelers and high-risk populations in endemic regions. Studies report that the highest incidence rate is found among children younger than 5 years and results in more severe disease than in earlier periods.^{604,609} *S. typhi* is increasingly resistant to ampicillin, chloramphenicol, and cotrimoxazole; even quinolone resistance is reported in many parts of the world.^{97,366} Case-fatality rates, which had decreased from 10% to 1% with appropriate antibiotic therapy, could rise again without safe, effective, and affordable vaccination strategies, especially as rates of resistance increase across the globe.

Preparations

The three types of typhoid vaccines are inactivated, whole-cell vaccines; live attenuated bacterial vaccines; and subunit vaccines.⁵⁰³ The parenteral, heat-phenol-inactivated, whole-cell vaccine widely used for many years was highly immunogenic but also was highly reactogenic and no longer is available in the United States. It is the only vaccine approved for use in children as young as 6 months and is still available in several developing countries because of its affordability, although the manufacture of this vaccine may not be up to international standards.

Two vaccines are licensed for use in the United States: an oral live, attenuated vaccine (TY21a, Vivotif Berna) and a purified Vi (virulence) capsular polysaccharide of *S. typhi* vaccine (ViCPS) (Typhim Vi, Aventis Pasteur) for intramuscular use. Table 245.20 provides information on

TABLE 245.20 Dosage and Schedule for Typhoid Fever Vaccination

Vaccination	Age (y)	Dose/Route of Administration	No. of Doses	Dosing Schedule	Boosting Interval
Oral Live Attenuated TY21a Vaccine					
Primary series	≥6	1 capsule ^a /oral	4	Days 0, 2, 4, 6	NA
Booster	≥6	1 capsule ^a /oral	4	Days 0, 2, 4, 6	Every 5 y
Vi Capsular Polysaccharide Vaccine					
Primary series	≥2	0.50 mL/IM	1	NA	NA
Booster	≥2	0.50 mL/IM	1	NA	Every 2 y

^aAdminister with cool liquid no warmer than 37°C (98.6°F).

NA, Not applicable.

Modified from Jackson BR, Iqbal S, Mahon B, et al. Updated recommendations for the use of typhoid vaccine—Advisory Committee on Immunization Practices, United States, 2015. *MMWR Morb Mortal Wkly Rep.* 2015;64:305–8.

vaccine dosage and administration. The time required for primary vaccination is different for the two vaccines, as are the lower age limits for use in children.

Ty21a is an oral, live attenuated vaccine consisting of a stable mutant, Ty21a, developed by chemical mutagenesis of a pathogenic *S. typhi* strain. This vaccine was licensed in the United States in 1989 for use in adults and children 6 years or older and is available as an enteric-coated capsule (i.e., must be swallowed whole). The four-dose primary vaccine series in the United States and Canada (three-dose series in other parts of the world) is administered as one capsule every other day, taken 1 hour before a meal, for a total of four capsules. The capsules should be kept refrigerated (not frozen), and all four doses must be taken to achieve maximum efficacy. Each capsule should be taken with cool liquid no warmer than 37°C (98.6°F) approximately 1 hour before a meal. This regimen should be completed 1 week before potential exposure. The vaccine manufacturer recommends that Ty21a not be administered to infants or children younger than 6 years.

A parenteral subunit vaccine, ViCPS, was licensed in 1994 for use in adults and children as young as 2 years of age. Primary vaccination with ViCPS consists of one 0.5-mL (25-μg) dose administered intramuscularly and should be given at least 2 weeks before potential exposure. The manufacturer does not recommend the vaccine for children younger than 2 years.

Various protein conjugated Vi polysaccharide vaccines have been developed and are used in countries other than the United States. Two were recently licensed in India for use in children 3 months or older.^{366,631}

In circumstances of continued or repeated exposure to *S. typhi*, booster doses are recommended to maintain immunity after primary immunization. The optimal booster schedule for either vaccine has not been determined. Current recommendations for revaccination with either vaccine are provided in Table 245.20. No data have been reported comparing the use of one vaccine as a booster after primary immunization with the other.

Efficacy

Although field trials have demonstrated approximately 80% efficacy of typhoid vaccines in US travelers,⁴⁴⁶ no comparative studies have been performed.³⁶⁶ For the heat-phenol-inactivated, whole-cell vaccine, efficacy ranged from 51% to 88% and lasted for as long as 7 years. The oral, live attenuated Ty21a vaccine stimulates humoral (i.e., serum IgG and mucosal IgA antibodies) and cell-mediated immune responses. In trials of the Ty21a vaccine, efficacy ranged from 42% to 96% after administration of the initial series of three doses, with the lower efficacies seen in trials from areas with highly endemic disease.^{429,605} The optimal schedule for booster immunizations has not been determined for this vaccine. Protective immunity persisted for at least 7 years in field trials in endemic countries where herd immunity may have an effect.³²⁴ Revaccination is recommended with the same four-capsule regimen every 5 years for as long as continued exposure is likely to occur.

Immunization with ViCPS results in seroconversion, defined as a fourfold rise in serum anti-Vi antibody, in 80% of vaccinees within 2 weeks in endemic and nonendemic areas.^{324,342,397} Because the vaccine

is administered parenterally, mucosal immunity does not develop. The efficacy of ViCPS vaccine in clinical trials was 72% at 17 months² and 64% at 21 months³⁹⁷ after administration of a single dose. A cluster-randomized trial in India enrolling 37,673 children 2 years or older demonstrated 61% effectiveness.⁶²⁹ Polysaccharide vaccines do not stimulate T cells and cannot establish immunologic memory. Additional doses of ViCPS therefore do not elicit a booster effect. Revaccination with a single dose is recommended every 2 years for people who remain at risk.

Conjugate Vi vaccines trials have used various carrier proteins, and one study of more than 12,000 children 2 to 5 years old demonstrated 90% efficacy over a trial period of 4 years using recombinant exoprotein A of *Pseudomonas aeruginosa* (Vi-REPA).⁴³⁴ Anti-Vi IgG titers were higher and longer lasting with conjugate Vi vaccines compared with Vi alone in adults and children from endemic areas.⁶³¹

None of the typhoid vaccines approaches 100% efficacy, and a large inoculum of *S. typhi* can overcome vaccine-induced immunity. Vaccinees do not substitute for proper hygiene and appropriate food handling practices.

Adverse Events

Reactions to the oral Ty21a vaccine usually are mild and consist of transient gastrointestinal upset, fever, headache, and an occasionally rash. These reactions occur in less than 5% of recipients.³⁶⁶ Adverse systemic effects are reported in less than 1% of vaccinees, and neither the development of bacteremia nor person-to-person transmission has been reported.³²⁴

Reactions to the ViCPS vaccine also occur infrequently and are reported in approximately 7% of recipients.³⁶⁶ These reactions include tenderness at the injection site, erythema and induration, fever, and rarely, rashes. Systemic complaints occur in less than 2%.³²⁴ In contrast, reactions to the inactivated, whole-cell vaccine occur more commonly and are more severe; they include fever in as many as 24% of recipients, headache, and severe local pain or swelling in as many as 35% of vaccinees. Between 13% and 24% of vaccinees have missed school or work because of adverse reactions.⁴³⁰

Reactions to the conjugate Vi vaccines were mild and limited to fever and mild erythema. There were no serious adverse events.^{434,631}

Indications

Typhoid vaccination in the United States is recommended only for the following groups:^{366,503}

- Travelers in areas where typhoid fever is endemic and for whom the risk of exposure is recognized; risk of exposure is greatest with travel to the Indian subcontinent, Latin America, Asia, the Middle East, and Africa
- People with intimate exposure to a documented *S. typhi* carrier, as occurs with continuing household contact
- Laboratory workers who have frequent contact with *S. typhi* and people living in areas outside the United States with endemic typhoid infection

Vaccination is not recommended for people attending summer camp or for those in areas of natural disaster or for control of common-source

outbreaks. Doses and schedules for the different typhoid vaccines are given in the recommendations of the CDC.^{366,503}

Contraindications

Ty21a is a live attenuated vaccine and should not be given to immunocompromised patients, including those receiving high doses of corticosteroids and people with HIV infection.^{366,503} Ty21a vaccine also should not be administered during a gastrointestinal illness or concurrent with certain antibiotics. The 2015 *Red Book* recommends avoiding antimicrobial therapy for at least 24 hours before the first dose of oral typhoid vaccine through 7 days after the last dose.⁴⁵ Reports are conflicting regarding the use of the antimalarial agents atovaquone and proguanil; however, chloroquine and mefloquine do not appear to interfere with the immune response to oral Ty21a. Neither of the available typhoid vaccines should be given to anyone with a history of severe local or systemic reactions after receiving a previous dose of vaccine.

Ty21a is not approved for children younger than 6 years, and ViCPS is not approved for children younger than 2 years. The whole-cell, inactivated vaccine available outside of the United States is approved for use in children between 6 months and 2 years of age.

Information is not available on the safety of these vaccines when they are used during pregnancy. It is prudent on theoretical grounds to avoid vaccinating pregnant women.

Yellow Fever Vaccine

Yellow fever occurs only in sub-Saharan Africa and tropical South America, where it causes an estimated 200,000 cases and 30,000 deaths annually.⁵⁶⁴ During the past 2 decades, 90% of all yellow fever cases were reported from countries in West Africa, where travelers are thought to be at the highest risk of travel-associated yellow fever.⁶¹⁷ Clinical disease ranges from a mild, nonspecific febrile illness to severe disease with jaundice and hemorrhage.

Yellow fever is an important vaccine-preventable disease among travelers to areas where yellow fever occurs. The yellow fever epidemic zones include Bolivia, Brazil, Colombia, Ecuador, French Guiana, Guyana, Paraguay, Peru, Suriname, Venezuela, and much of sub-Saharan Africa. From 1970 to 2013, 10 cases of yellow fever were reported in unvaccinated travelers from the United States and Europe who traveled to West Africa (five cases) or South America (five cases). The unvaccinated traveler's risk of acquiring yellow fever probably is increasing because potential zones of transmission of yellow fever are expanding to include urban areas with large populations of susceptible humans and abundant competent mosquito vectors. Vaccination is the most effective preventive measure against yellow fever, a disease that has no specific treatment and may cause the death of 20% to 50% of patients.⁴⁸⁴

Preparations

Yellow fever vaccines are derived from the original 17D yellow fever vaccine strain. The live attenuated 17D-204 and 17DD yellow fever strains are the yellow fever vaccines most commonly used.⁴⁸⁴ The only yellow fever vaccine licensed in the United States is the 17D-204 vaccine, which is prepared in chick embryos (YF-Vax, Sanofi Pasteur).⁶¹⁸

Primary immunization consists of a single, subcutaneous injection of 0.5 mL of reconstituted, freeze-dried vaccine for adults and children. The vaccine should be stored at 2°C to 8°C. Because the vaccine does not contain a preservative, reconstituted vaccine that remains unused after 1 hour must be properly disposed.

Immunogenicity and Efficacy

Seroconversion rates of 93% have been documented for young children receiving yellow fever vaccine.⁷¹⁰ Thirteen observational studies showed a seropositivity rate of 92% at least 10 years after receiving the vaccine and 80% at least 20 years after vaccination.⁶¹⁷ Immunity develops by the tenth day after primary vaccination. The titer of virus-neutralizing antibodies in the sera of vaccinees is used as a surrogate for vaccine effectiveness.

No human efficacy studies have been performed with yellow fever vaccine. However, the number of yellow fever cases was substantially reduced after the introduction of the vaccine, supporting its protective role in humans. Worldwide, only 18 cases of yellow fever have been

reported in vaccine recipients after the administration of more than 540 million doses; 16 (89%) had received a vaccine dose within the previous 10 years.⁶¹⁷

Adverse Events

The 17D-204 and 17DD yellow fever vaccines are among the safest and most effective viral vaccines.⁴⁸⁴ Since 1965, approximately 8 million doses of 17D-derived yellow fever vaccine have been administered to US travelers, and approximately 300 million doses have been administered to people in areas where yellow fever is endemic. Although 10% to 30% of people who receive vaccine report headaches, myalgia, and low-grade fever that begin within a few days after vaccination and last 5 to 10 days, less than 1% report temporarily curtailing their usual activities.

Historically, yellow fever vaccine-associated adverse events were seen primarily among infants and manifested as encephalitis. However, with the current yellow fever vaccine, serious adverse events associated with vaccine rarely occur. A systematic review found that no serious adverse events were reported in four RCTs of infants and children ($n = 1866$).⁶³⁶

Three well-characterized serious adverse events may occur after yellow fever vaccine administration: immediate hypersensitivity or anaphylactic reactions, yellow fever vaccine-associated neurologic disease (YEL-AND), and yellow fever vaccine-associated viscerotropic disease (YEL-AVD). Immediate hypersensitivity reactions, characterized by rash, urticaria, or bronchospasm, or a combination of these features is uncommon (1.8 cases/100,000 doses). Unrecognized allergy to eggs or chicken or to the hydrolyzed gelatin used to stabilize the vaccine may be responsible for hypersensitivity reactions.

YEL-AND is a serious but rarely fatal adverse event that occurs among people of all ages. YEL-AND manifests as several distinct clinical syndromes, including meningoencephalitis (i.e., neurotropic disease), Guillain-Barré syndrome, acute disseminated encephalomyelitis (ADEM), and bulbar palsy, starting 3 to 28 days after vaccination, usually in first-time recipients.¹⁴⁰ Meningoencephalitis occurs as a result of direct yellow fever vaccine viral invasion of the central nervous system (CNS) with infection of the meninges or the brain, or both. The other neurologic syndromes (e.g., Guillain-Barré syndrome, ADEM) represent autoimmune manifestations in which antibodies or T cells produced in response to the vaccine cross-react with neuronal epitopes and lead to central or peripheral nerve damage. The incidence of YEL-AND in the United States is 0.8 case per 100,000 doses.

In 2001, a previously unrecognized, potentially fatal adverse reaction among recipients of YF vaccine was first described. This syndrome previously was reported as febrile multiple organ dysfunction or failure and now is called yellow fever vaccine-associated viscerotropic disease. YEL-AVD mimics naturally acquired wild-type yellow fever disease, with the vaccine virus proliferating and disseminating throughout the host's tissues. Since it was initially described, more than 65 confirmed or suspected cases have been reported globally. On the basis of an analysis of cases for which information is available, YEL-AVD has occurred only after a recipient's first yellow fever vaccination; no cases of YEL-AVD occurring in people receiving booster doses of the vaccine have been reported. The median time from vaccination to disease onset is approximately 4 days. The case-fatality ratio for reported cases is approximately 60%. The incidence of YEL-AVD in the United States is 0.4 case per 100,000 doses.

Several risk estimates for YEL-AVD have been published. On the basis of VAERS data, the reporting rate of YEL-AVD is 3 to 4 cases per 1 million doses distributed.^{435,462}

The recognition of these adverse events may be challenging because the neurologic syndromes (e.g., encephalitis, myelitis) can be difficult to distinguish from bacterial meningitis, encephalitis, or malaria, and the viscerotropic syndrome can be difficult to distinguish from hemorrhagic fevers, viral hepatitis, and many other causes of multisystem failure.

Indications

Yellow fever vaccine is recommended for people 9 months or older traveling to or residing in areas where yellow fever is endemic.⁶¹⁸ Because of the increased risk of neurologic complications, infants 6 to 8 months of age should be considered for vaccination only when travel to high-risk

areas is unavoidable and high-level protection against mosquito exposure is not feasible. Infants younger than 6 months have a substantially increased risk of neurologic disease, and vaccination should not be given to this age group. Vaccination for international travel to certain destinations is required.

Yellow fever vaccination requirements for specific countries are available on the CDC Traveler's Health website (<http://wwwnc.cdc.gov/travel/yellowbook/2016/infectious-diseases-related-to-travel/yellow-fever>). To obtain an international certificate of vaccination, a yellow fever vaccine approved by the WHO and administered at a designated yellow fever vaccine center is required. Yellow fever vaccine centers in the United States can be identified by contacting state or local health departments or visiting the CDC website (<http://wwwnc.cdc.gov/travel/yellow-fever-vaccination-clinics/search>). If the risks of potential serious adverse events caused by the yellow fever vaccine are considered greater than the potential benefits for exposed individuals, a medical waiver letter can be provided, and guidance is provided on the CDC website (<http://wwwnc.cdc.gov/travel/yellowbook/2016/infectious-diseases-related-to-travel/yellow-fever#4731>).

Historically, the WHO international health regulations required revaccination at 10-year intervals. However, evidence from several studies indicated that yellow fever immunity persists for many decades. In 2015, the CDC's ACIP issued a recommendation that only a single dose of yellow fever vaccine is required to provide long-lasting protection for most travelers except for pregnant women, hematopoietic stem cell transplant recipients and HIV-infected people. The WHO has removed the booster requirement from the international health regulations as of 2016.⁶¹⁷

Yellow fever vaccines can be administered at the same time as inactivated vaccines and other live attenuated viral vaccines, except for the MMR vaccine, because the immune responses against yellow fever, mumps, and rubella are inhibited.⁴⁰⁸ These vaccines should be given 30 days apart.

Precautions and Contraindications

The risk of having adverse reactions appears to be age related.⁶¹⁸ Infants younger than 9 months should not receive yellow fever vaccine because of the increased risk of vaccine-associated neurotropic disease developing in this age group.³⁰ Immunization should be delayed until an infant is at least 9 months of age. In unusual circumstances, physicians considering vaccinating infants 6 to 8 months of age should contact the applicable division of the CDC for advice (i.e., CDC Division of Vector-Borne Infectious Diseases or the CDC Division of Global Migration and Quarantine: 800-232-4636).

No major adverse effects of yellow fever vaccine on the developing fetus have been demonstrated. A slight increased risk was observed for minor, mostly skin, malformations in infants. A higher rate of spontaneous abortions in pregnant women receiving the vaccine was reported but not substantiated. Vaccine administration to pregnant women usually is not indicated because the vaccine is a live virus. Pregnant women should be considered for vaccination only when travel to high-risk areas is required and protection against mosquito exposure is not feasible. Considering that immune responses to vaccination during pregnancy may vary, serologic testing can be considered to document a protective immune response to the vaccine.

Three YEL-AND cases have been reported in exclusively breastfed infants whose mothers were vaccinated with yellow fever vaccine. All three infants were younger than 1 month and diagnosed with encephalitis. Until more data are available, yellow fever vaccine should be avoided in breastfeeding women. However, when travel of breastfeeding mothers to a yellow fever–endemic area cannot be avoided, these women should be vaccinated.

Yellow fever vaccine, which is a live attenuated virus vaccine, poses a risk of developing encephalitis or other serious adverse events for patients with conditions that commonly result in immunosuppression (i.e. AIDS or symptomatic HIV infection, primary immunodeficiencies, thymic disease with abnormal immune function such as thymoma or myasthenia gravis, malignancy, transplantation, and radiation therapy). The vaccine should be avoided by these people. Although not specifically tested, the vaccine is presumed to pose risks for patients receiving

immunosuppressive or immunomodulatory therapies (e.g., high-dose systemic corticosteroids, alkylating drugs, antimetabolites, tumor necrosis factor- α inhibitors, interleukin-1 and interleukin-6 blocking agents, other monoclonal antibodies such as rituximab and alemtuzumab) and should be avoided in most cases according to the drug manufacturers. A history of thymectomy or indirect radiation therapy is not considered a contraindication.

Family members of immunosuppressed people, who themselves have no contraindications, may receive yellow fever vaccine. If travel to an epidemic or endemic area is necessary, the patient should be instructed in ways to avoid mosquitoes and given a vaccine waiver letter.

People with a history of systemic anaphylaxis to eggs or chicken should not be vaccinated because the vaccines contain egg proteins and on rare occasion may induce immediate allergic reactions. People may also develop allergies to the vaccine because it contains gelatin and latex from the vial stopper. Less severe or local manifestations of allergy to eggs or to feathers are not contraindications to yellow fever vaccine administration and do not warrant performing vaccine skin testing.³⁶ If international quarantine regulations are the only reason to immunize a patient known to be hypersensitive to eggs, a medical waiver letter should be provided. If immunization of an individual with a questionable history of egg hypersensitivity is considered essential because of the high risk of exposure, an intradermal skin test can be given as directed in the vaccine package insert.⁶¹⁸

Vaccines Related to Bioterrorism

Anthrax and smallpox vaccines are potentially available to protect children against bioterrorist attacks with *Bacillus anthracis* and variola. Anthrax vaccine is not approved by the FDA for use in children. The AAP updated its recommendations on exposure to anthrax through bioterrorism in 2014.⁸⁶ Until there are sufficient data to support FDA approval, anthrax vaccine will be made available for children at the time of an event as an investigational vaccine through an expedited process that requires institutional review board approval, including the use of appropriate consent documents. Information on the process required for use of anthrax vaccine in children will be available on the CDC website at the time of an event (<https://www.cdc.gov/anthrax/>).⁷⁰³

The only smallpox vaccine licensed in the United States is ACAM2000, a live virus vaccine.¹⁵³ In the absence of a smallpox outbreak, preexposure smallpox immunization is not recommended for children.⁴⁶ Anthrax and smallpox vaccines are reviewed in the relevant disease-specific chapters of this textbook.

Investigational Vaccines

Routine immunizations for children have virtually eliminated many infectious diseases from the United States. These successes have encouraged research to develop vaccines to prevent other serious viral and bacterial diseases affecting children. A 1985 report by the IOM of the National Academy of Sciences reviewed the benefits that would be associated with the development and use of new and improved vaccines in the United States.²¹² The report listed 14 diseases for which vaccines were desirable. A 1999 study by the IOM observed that considerable progress had been made since the 1985 study.²¹³ Seven of 14 vaccines listed in the 1985 study as domestic priorities for development are now licensed. They include acellular pertussis vaccine, LAIV, and vaccines against hepatitis A and B, Hib, varicella, and rotavirus.

The 1999 IOM report used a new quantitative model to compare the cost and health benefits of developing candidate vaccines.²¹³ This model can be used to evaluate the potential impact of a new vaccine on public health. In the 1999 report, the model was used to evaluate diseases for which candidate vaccines were being developed. The report divided 26 candidate vaccines into four groups, arranged from most to least favorable for development. The four vaccines in the top tier include a cytomegalovirus vaccine given to adolescents, a universal influenza vaccine, a group B *Streptococcus* vaccine for high-risk adults and pregnant women, and an *S. pneumoniae* vaccine for infants and seniors. Other diseases for which vaccines would be desirable included *Chlamydia trachomatis*, enterotoxigenic *E. coli*, Epstein-Barr virus, *Helicobacter pylori*, hepatitis C virus, herpes simplex virus, human papilloma virus (HPV), *M. tuberculosis*, *Neisseria gonorrhoeae*, respiratory

BOX 245.2 Pathogens With Important Public Health Implications That Have No Licensed Vaccines

Campylobacter jejuni
 Chikungunya virus
 Dengue virus
 Enterotoxigenic *Escherichia coli*
 Enterovirus 71 (EV71)
 Group B *Streptococcus* (GBS)
 Herpes simplex virus
 Human immunodeficiency virus type 1 (HIV-1)
 Influenza virus (i.e., no universal vaccine)
Leishmania spp. (i.e., leishmaniasis)
Mycobacterium tuberculosis (i.e., tuberculosis)
Necator americanus and *Ancylostoma duodenale* (i.e., human hookworm disease)
 Nipah virus
 Nontyphoidal *Salmonella* spp. (i.e., salmonellosis)
 Norovirus
Plasmodium spp. (i.e., malaria)
 Respiratory syncytial virus (RSV)
Salmonella enterica subspecies (i.e., paratyphoid fever)
Schistosoma mansoni, *S. haematobium*, and *S. japonicum* (i.e., schistosomiasis)
Shigella spp. (i.e., shigellosis)
Staphylococcus aureus
Streptococcus pneumoniae
Streptococcus pyogenes
Trypanosoma cruzi (i.e., Chagas disease)
 Zika virus

syncytial virus, parainfluenza virus, *Shigella*, and groups A and B streptococci. Two vaccines listed in the 1999 study are now licensed: pneumococcal conjugate vaccine for infants and seniors and HPV vaccine.

Progress in vaccine development is periodically reviewed and published by National Institute of Allergy and Infectious Diseases (NIAID) scientists in The Jordan Report.⁴⁹⁷ The 2012 report discusses progress in vaccine development and states that we now have licensed vaccines against Hib and pneumococcal types that cause high childhood morbidity and mortality rates, against hepatitis A and B, against rotaviruses, and against varicella. We also have improved vaccines against such diseases as influenza and pertussis.

Advances in biotechnology, increased understanding of the virulence factors of infectious agents, and knowledge of the host immune response have led to new approaches for vaccine development.²⁵⁶ Technological advances in making vaccines, including protein conjugation of bacterial polysaccharides, DNA vaccines, viral chimeras, viral vectors, and other novel platforms have been developed. Vaccines are being developed by the application of these newer technologies to numerous infectious agents for which effective vaccines are not currently available. The development of vaccines for these pathogens requires solution of several immunologic problems, including pathogen variability, short effector memory, evoking functional responses, and identification of antigens that generate protective responses.⁵³⁹

The 2012 Jordan Report states that many challenges remain. Progress on vaccines to prevent some high-burden diseases has been frustratingly slow, although there is a growing pipeline of novel vaccines against dengue, malaria, tuberculosis, and others. The Report lists approximately 600 vaccine candidates in development against an estimated 110 pathogens. Considering the resource constraints in vaccine development, approaches that are most likely to produce high-priority vaccines need to be identified.

A special issue of *Vaccine* published in June 2016 focuses on the research and development pipeline of vaccines against 25 pathogens for which no licensed vaccines currently exist but for which there is

high public health importance, as identified by the WHO Product Development for Vaccines Advisory Committee (PDVAC).⁶⁸⁷ PDVAC is a body of independent experts that was established in 2014 to guide the WHO and the vaccine development community along the pathway toward the goal of licensure and deployment in countries with the highest disease burden. These vaccines are listed in [Box 245.2](#).

Passive Immunization

246

Danica J. Schulte

PRINCIPLES OF PASSIVE IMMUNITY

Definition

Passive immunization is the administration of antibodies to provide immediate protection against a microbial agent, or toxin. Passive immunization is used to provide temporary immunity in an unimmunized person exposed to an infectious disease when active immunization is unavailable (e.g., respiratory syncytial virus [RSV] infection), is contraindicated (e.g., varicella in an immunocompromised child), or has not been given before exposure (e.g., tetanus, rabies).

Passive immunization also is used in the management of certain disorders associated with toxins (e.g., diphtheria), for certain bites (e.g., snake, spider), in drug overdose (e.g., digoxin), as a specific (e.g., Rh0[D] immunoglobulin) or nonspecific (e.g., antithymocyte globulin) immunosuppressant, and in the treatment of certain infectious diseases.

The following four types of preparations are used in passive immunization ([Table 246.1](#)):

1. Standard human immune serum globulin (HISG) for general use, which is available as immunoglobulin for intramuscular use (IGIM), intravenous use (IGIV), and subcutaneous use (IGSC)
2. Special high-titer immunoglobulins with a known antibody content for specific illnesses
3. Animal sera and antitoxins
4. Monoclonal antibodies ([Table 246.2](#))

Most of the licensed special immunoglobulins are for intramuscular use only. Plasma, serum, and breast milk also can be used in passive immunization.

Passive immunization is not always effective. The duration is short, varying between 1 and 6 weeks. Undesirable reactions can occur, especially if the antibody is of nonhuman origin. High-titer special

TABLE 246.1 Antibody Preparations Available for Passive Immunity in the United States

Product	Abbreviations and Brand Names	Principal Use
Standard Human Immune Serum Globulins for Intramuscular or Subcutaneous Use		
Immunoglobulin, intravenous	IGIV, IVIG	Treatment of antibody deficiency, immune thrombocytopenic purpura, Kawasaki disease, other immunoregulatory and inflammatory diseases
Immunoglobulin, intramuscular	IGIM, IG, ISG	Treatment of antibody deficiency; prevention of measles, hepatitis A
Immunoglobulin, subcutaneous	IGSC	Treatment of antibody deficiency
Special Human Immune Globulins for Intramuscular or Subcutaneous Use		
Hepatitis B immunoglobulin	HBIG, HyperHEP B, Nabi-HB, HepaGamB	Prevention of hepatitis B
Varicella-zoster immunoglobulin	VariZIG	Prevention or modification of chickenpox
Rabies immunoglobulin	RIG	Prevention of rabies
Tetanus immunoglobulin	TIG	Prevention or treatment of tetanus
Vaccinia immunoglobulin	VIG, VIGIM	Prevention or treatment of vaccinia, prevention of smallpox
RhO(D) immunoglobulin	RhoGAM, MICRhoGAM, HyperRHO S/D, BayRho-D	Prevention of Rh hemolytic disease
Special Human Immunoglobulins for Intravenous Use		
Cytomegalovirus immunoglobulin	CMV-IGIV, CMVIG, CytoGam	Prevention or treatment of cytomegalovirus infection
Hepatitis B immunoglobulin, intravenous	HBIGIV, HepaGam B, Nabi-HB NovaPlus	Prevention of hepatitis B (including liver transplantation)
Vaccinia immunoglobulin, intravenous	VIGIV	Prevention or treatment of vaccinia, prevention of smallpox
RhO(D) immunoglobulin, intravenous	WinRho SDF, Rhophylac	Treatment of immune thrombocytopenic purpura
Botulinum immunoglobulin	BIG, BabyBIG	Treatment of newborn botulism
Animal Sera and Globulins		
Tetanus antitoxin (equine)	TAT	Prevention or treatment of tetanus (when TIG is unavailable)
Diphtheria antitoxin (equine)	DAT	Treatment of diphtheria
Botulinum antitoxins (equine)	BAT	Treatment of botulism
<i>Latrodectus mactans</i> antivenin (equine)	Antivenin	Treatment of black widow spider bites
Crotalidae polyvalent antivenin (equine)	—	Treatment of most snake bites
Crotalidae polyvalent immune Fab (ovine)	—	Treatment of most snake bites
<i>Micrurus fulvius</i> antivenin (equine)	—	Treatment of coral snake bites

immunoglobulins and IGIVs are identical to regular immunoglobulins and IGIv's, except that they are derived from patients hyperimmunized or convalescing from a specific infection or selected from donors with high titers in response to a specific antigen. They are useful in several disorders in which regular immunoglobulin and IGIV are of little or no value.

Animal Sera and Antitoxins

Animal sera and antitoxins are derived from the serum of immunized animals, usually horses (i.e., equine formulations). Because these sera are foreign proteins, they carry a significant risk for sensitization. They should be administered only when specifically indicated, after sensitivity tests, and by a physician prepared to deal with a hypersensitivity reaction.

A careful medical history must be obtained before an animal serum is injected. Patients must be asked about asthma, hay fever, urticaria, and previous injections of animal serum. Patients with a history of asthma, allergic rhinitis, or other allergic symptoms on exposure to horses may be dangerously sensitive to the corresponding serum, and the serum should be given only with the utmost caution.

Sensitivity Tests for Animal Serum

A skin prick test, followed by an intradermal skin test, always should be performed before injection of an animal serum, regardless of whether the patient has had the serum previously.²³ A skin prick test is performed by applying a drop of a 1:100 dilution of the serum in saline to the site of a superficial scratch, prick, or puncture on the volar aspect of the forearm and observing it for 20 minutes. A positive control (i.e., 0.1% histamine phosphate) and negative control (i.e., saline) should also be applied. A positive reaction consists of erythema with wheal formation 3 mm greater than the negative control. However, previous use of antihistamines may render results of these tests negative.

If the skin prick test result is negative, an intradermal test is performed by injecting 0.02 mL of a 1:1000 saline dilution; positive (i.e., 0.1%

histamine phosphate) and negative control tests should be performed. The reaction is read 10 to 30 minutes after the injection and is positive if a wheal appears that is 3 mm greater than the negative control. If the test result is negative, it should be repeated with 0.02 mL of a 1:100 dilution. For people with a negative history of animal allergy and no previous exposure to animal sera, the 1:100 dilution may be used initially if the skin prick test result is negative.

Although intradermal skin tests have resulted in fatalities, skin prick tests have not, but they can still be associated with immediate reactions. A skin test never should be performed or serum injected unless a syringe containing 1 mL of 1:1000 epinephrine is within immediate reach and supportive care is available.

Skin tests can indicate the probability of sensitivity. However, a negative skin test result does not guarantee the absence of sensitivity. A specific history of allergy or a positive skin test reaction with horse serum is sufficient reason for special caution. A positive history of sensitivity to horse dander is an indication of the need for extreme caution.

Administration of Animal Serum

If the history and sensitivity test reactions are negative, the indicated dose of serum may be given intramuscularly, with epinephrine at hand.²³ The patient should be watched closely for an hour for adverse reactions.

Intravenous injection may be indicated if a high concentration of circulating antibody is required rapidly, as in botulism or diphtheria. The manufacturer's instructions should be consulted.

If the skin test reaction is positive or there is a history of allergy to animal serum but the need for the serum is unquestioned (and epinephrine is at hand), a procedure commonly referred to as desensitization can be undertaken, although any significant desensitization is unlikely to occur. This procedure establishes temporary tolerance to the serum. Desensitization should be performed by trained personnel with the necessary emergency equipment and drugs immediately available.

TABLE 246.2 US-Adopted Nomenclature for Monoclonal Antibodies

The suffix *-mab* or *-nab* is used for all monoclonal antibodies and fragments. Letters preceding the suffix identify the product source.^a

Letter	Source
u	Human
e	Hamster
o	Mouse
i	Primate
a	Rat
xi	Chimeric
zu	Humanized
The disease state targeted by the monoclonal antibody is specified by a syllable preceding one of the letters above. ^b	
Syllable	Target Disease or System
–vir	Viral disease
–bac	Bacterial disease
–lim	Immune system
–les	Infectious lesions
–circ	Cardiovascular system
Syllable	Tumors
–col	Colon
–mel	Melanoma
–mar	Mammary
–got	Testis
–gov	Ovary
–pr(o)	Prostate
–tum	Miscellaneous

^aExamples are *o* for mouse, as in *muromonab*, and *u* for human, as in *adalimumab*.

^bCombinations of target and source designations result in endings such as *–limumab* (i.e., immune system, human) and *–ciximab* (i.e., circulatory system, chimeric, with the consonant *r* dropped).

Desensitization consists of periodic (i.e., 15-minute intervals) injections or infusions of progressively larger doses of the serum, starting at a very low dose, until tolerance is achieved. Schedules for intravenous and intradermal, subcutaneous, or intramuscular desensitization are given in the *2015 Red Book*.²³ Administration of sera after desensitization has been achieved must be continuous or protection from desensitization is lost rapidly.

Hypersensitivity Reactions to Animal Serum

Hypersensitivity reactions to animal serum are of four general types:

1. Anaphylactic reactions consisting of urticaria or other rashes; respiratory distress with wheezing, dyspnea, cough, hoarseness, or stridor; cardiovascular reactions, including tachycardia, hypotension, arrhythmia, cyanosis, shock, and unconsciousness; and gastrointestinal reactions, such as cramps, diarrhea, and vomiting, all occurring seconds to minutes after an injection has been administered
2. Acute febrile reactions consisting of moderate or severe hyperpyrexia within 2 hours after an injection has been given
3. Serum sickness reactions consisting of urticaria, arthritis, adenopathy, and fever occurring hours to days after an injection has been administered, depending on the dose and the presence or degree of previous sensitization (i.e., serum sickness occurs within hours or a few days after the second injection and within 7 to 12 days after the first injection)
4. Various delayed reactions, including peripheral neuritis, nephritis, Guillain-Barré syndrome, and myocarditis

Treatment of Hypersensitivity Reactions to Animal Serum

For anaphylactic reactions, 1:1000 epinephrine at a dose of 0.01 mL/kg (maximum dose, 0.5 mL) is given subcutaneously or intramuscularly immediately. If improvement is not achieved immediately, 1:10,000

epinephrine at a dose of 0.01 mL/kg is given intravenously. This dose can be repeated every 10 minutes for up to three doses. The 1-mL 1:1000 epinephrine vials must be diluted 1:10 in physiologic saline (i.e., 1:10,000) and injected slowly at a dose of 0.01 mL/kg; a 1:10,000 dilution in a 10-mL vial also is available.

Administration of epinephrine may be repeated in 5 to 15 minutes if the response is not satisfactory. Vasopressors and positive-pressure oxygen are helpful. For severe urticaria or edema, particularly edema of the larynx, intramuscular injection of antihistamines and corticosteroids is indicated. Administration of serum therapy (if necessary) should be resumed 6 to 8 hours later or after all visible signs of reaction have subsided.

Mild febrile reactions (temperatures <39°C [$<102.8^{\circ}\text{F}$]) are treated with ibuprofen or acetaminophen. Severe febrile reactions can cause seizures and death and should be treated rigorously with sponge baths or other cooling means to reduce the temperature promptly. Serum sickness and serum neuritis usually are treated with corticosteroids.

Human Immune Serum Globulin

HISG, or gamma globulin, is available in three forms for general use: IGIM, IGIV, and IGSC. IGIM is used primarily for the prevention of certain infectious disorders and less commonly for the treatment of antibody immunodeficiencies. IGIV is used in the treatment of primary and secondary antibody deficiencies, many immunoregulatory disorders (e.g., immune thrombocytopenic purpura, Kawasaki disease), and neurologic disorders (e.g., Guillain-Barré syndrome, peripheral neuritis). IGSC is used exclusively for the treatment of antibody deficiency.

Intramuscular Immunoglobulin

Pharmacology. IGIM is prepared from pooled human serum by the Cohn alcohol fractionation procedure, thereby deriving its alternative name of Cohn fraction II. This procedure and viral inactivation steps remove most other serum proteins, hepatitis viruses, and human immunodeficiency viruses (i.e., HIV-1 and HIV-2), thereby providing a safe product for intramuscular injection. It is reconstituted as a sterile, approximately 16% solution (160 mg/mL) with or without preservative. It contains a wide spectrum of antibodies to viral and bacterial antigens.

IGIM is greater than 95% immunoglobulin G (IgG), but trace quantities of IgM and IgA and other serum proteins are present. IgM and IgA are therapeutically insignificant because of their rapid half-lives (about 7 days) and low immunoglobulin concentrations. Immunoglobulin contains all IgG allotypes (i.e., GM and KM allotypes, which are antigenic determinants on γ and κ light chains, respectively).

IGIM is approved only for intramuscular or subcutaneous use, and intravenous injection of IGIM usually is contraindicated. IGIM aggregates in vitro to high-molecular-weight complexes (i.e., 9.5S to 40S) that are strongly anticomplementary. These aggregates probably are responsible for the occasional systemic reactions to IGIM. The incidence of these reactions is increased if the patient has received IGIM previously or if it is inadvertently given intravenously. Agammaglobulinemic boys with affected male relatives (suggesting X-linked inheritance) may have a lower incidence of reactions.⁴⁷¹ Small intradermal injections of IGIM are not of value except as a placebo, and they are contraindicated.

Intramuscular immunoglobulin in antibody immunodeficiency. IGIM is used infrequently for IgG replacement therapy in immunodeficiency. The usual dosage is 100 mg/kg per month, about equivalent to 0.7 mL/kg per month of the 16% (160 mg/mL) product. Two or three such injections are given at the onset of therapy as a loading dose, often over a 3- to 5-day period. The maximal maintenance dosage should not exceed 20 or 30 mL/wk.

Few studies on optimal dosage are available. However, the Medical Research Council Working Party⁴⁷¹ found that 25 mg/kg per week (100 mg/kg per month) was therapeutically equivalent to 50 mg/kg per week but that 10 mg/kg per week was inadequate. Use of IGIM by this route has been supplanted largely by IGIV administration.

IGIM should be given at multiple sites to avoid giving more than 5 mL at any one site (i.e., 10 mL in a large adult). The buttocks are the preferred site, but the anterior of the thighs also can be used. Tenderness, sterile abscesses, fibrosis, and sciatic nerve injury may result from these

injections. The danger of sciatic nerve injury is especially great in a small malnourished infant with inadequate muscle and fat in the gluteal regions. Large doses of IGIM should not be given to patients with severe thrombocytopenia because of the risk for development of hematoma and infection.

The injections are given initially at monthly intervals. If the patient continues to have infection or if a characteristic symptom (e.g., cough, conjunctivitis, diarrhea, arthralgia, purulent nasal discharge) recurs at the end of the injection period, the interval between doses is decreased to 3 or 2 weeks. Because IgG catabolism increases during acute infections, extra injections of IGIM often are given.

Because high serum levels of IgG cannot be maintained, serial immunoglobulin assays are unnecessary in assessing the effectiveness of treatment. The maximal increase in serum IgG level after a standard IGIM injection varies from patient to patient and from dose to dose because of different rates of absorption, local proteolysis at the injection site, and distribution within tissues.

An intramuscular injection of 100 mg/kg of IGIM usually raises the IgG serum level by 100 mg/dL after 2 to 4 days.⁶⁶⁹ A recent IGIM injection usually does not obscure the diagnosis of hypogammaglobulinemia.

Intramuscular immunoglobulin and special intramuscular immunoglobulins for prevention of infectious diseases. IGIM is recommended for prophylaxis of hepatitis A and measles. The recommended doses are found in the sections on these disorders. Special high-titer IGIMs are available for several disorders, such as hepatitis B and varicella. These products are identical to IGIM except for the high titers of specific antibodies. These products also are discussed in the sections on these disorders.

Adverse effects of intramuscular immunoglobulin. Rare anaphylactic reactions to intramuscular injections of immunoglobulin have been reported, particularly in patients requiring repeated injections.²⁰⁸ The Medical Research Council Working Party⁴⁷¹ observed these reactions in 33 (19%) of 175 patients treated during a 10-year period. After approximately 40,000 injections, 85 reactions occurred; in eight patients, the injections were stopped as a result of these adverse effects, and one death was recorded. The reactions occurred at any stage of treatment and were unrelated to any particular lot number of IGIM or its anticomplementary activity. Symptoms include anxiety, nausea, vomiting, malaise, flushing, facial swelling, cyanosis, and loss of consciousness. Immediate treatment with epinephrine and antihistamines is indicated.

People who experience these reactions should be evaluated before receiving a repeat injection. Skin testing should be performed with several lots of IGIM.²⁰⁸ A skin test result that is positive for an old but not a new lot of immunoglobulin may indicate a particular idiosyncratic reaction to a particular lot. Under these circumstances, incremental doses of immunoglobulin from a new lot are recommended. In other patients, IgE antibodies to IgG develop and result in positive, immediate skin test reactions to all IGIM lots. In many other patients, no cause of the reactions can be found. Some of these patients can tolerate gradually increasing doses of immunoglobulin, particularly if they are premedicated with a nonsteroidal antiinflammatory agent, diphenhydramine, or corticosteroids. In a few patients, antibodies have developed to the IgA present in minute quantities in immunoglobulin, and these IgA antibodies can be detected by serology.⁷⁴³ This topic is discussed further in the Adverse Effects of Intramuscular Immunoglobulin section.

Administration of exogenous gamma globulin may inhibit the endogenous synthesis of gamma globulin. In a few patients given IGIM or IGIV from early infancy, depressed IgG levels returned to normal when the injections were stopped. Amer and colleagues²⁰ reported decreased IgG levels in premature infants given monthly IGIM injections since birth.

IGIM injections or infusions can inhibit antibody responses to live virus vaccines such as measles or varicella. Siber and associates⁶⁴⁰ recommend an interval of 3 months between IVIG or IGIM therapy and administration of live virus vaccines after immunoglobulin doses of less than 40 mg/kg, an interval of 6 months after doses of 40 to 80 mg/kg, an interval of 8 months after doses of 80 to 400 mg/kg, and an interval of 12 months after large doses (1–2 g/kg).²³

Late side effects after IGIM injections are uncommon occurrences, but fibrosis of the buttocks or localized subcutaneous atrophy may

develop at the site of repeated injections in some patients. Repeated injections of IGIM may result in high levels of mercury from the thimerosal preservative. Although symptoms of acrodynia (i.e., mercury toxicity) developed in one patient as a result of such therapy,⁴⁵⁷ most remained asymptomatic.

Intravenous Immunoglobulin

IGIV is further-treated Cohn fractionated human immunoglobulin that has been rendered free of complexes and is safe for intravenous infusion. These products can be given in large quantities for antibody deficiencies¹²⁴; for several autoimmune, inflammatory, and neurologic disorders^{64,201}; and for prevention of transplant rejection.^{350,351}

Pharmacology. The first IGIV produced in the United States in 1981 was Gamimune, a reduced and alkylated 5% solution containing 10% maltose.⁴¹ The second IVIG produced was prepared by acidification and treatment with pepsin; the lyophilized powder could be reconstituted as a 3%, 6%, or 12% solution (Sandoglobulin). Since then, several IGIVs have been introduced by different manufacturers.⁵²⁸

Several methods of treating Cohn fraction II, including treatment with proteolytic enzymes, ultracentrifugation, chromatography, reduction of sulfhydryl bonds by alkylation, and incubation at low pH, have been used to eliminate high-molecular-weight complexes. Solvent and detergent treatment, pasteurization, and addition of the fatty acid caprylate are used to ensure that viral inactivation occurs,³⁰⁹ and various stabilizers, such as maltose, albumin, or sucrose, are then added. Variations in manufacturing techniques result in unique characteristics in the different immunoglobulin products.⁵²⁸

Although these products vary somewhat across brands and batches,^{550,668} they are for the most part therapeutically equivalent and usually are selected on the basis of cost and convenience. IgG subclass differences exist.^{46,650} Antibody titers to specific pathogens also may vary across lots and among different IGIVs.²³⁴ Products have different IgA contents, which can be a consideration for patients with anti-IgA antibodies.⁴⁶ Premixed liquids have the advantage of convenience because the reconstitution step is not required; however, most solutions must be kept refrigerated.

The IGIV products currently available have all IgG subclasses, adequate serum half-lives (i.e., 15 to 25 days), a wide spectrum of antibody activity, and minimal anticomplementary activity, and they are free of bacterial and viral contamination.³²⁹ Individual donors are checked for viral pathogens, and the final product is checked for sterility. The ability of the fractionation process to remove viral and prion particles is validated by spiking test pools with model pathogens and subjecting them to the same fractionation process used by the plasma pools for human use. Some of them are 5% to 10% solutions, and others are lyophilized powders that are reconstituted as 3% to 12% solutions.^{528,670}

IGIV has several advantages over IGIM. Larger quantities of IgG can be given, high levels of serum IgG can be achieved rapidly, painful intramuscular injections are avoided, tissue pooling and local proteolysis are avoided, and home administration and self-administration are easier to perform.

Administration of intravenous immunoglobulin. Administration of IGIV requires venous access, which is sometimes a problem in small children or obese patients. It also requires close monitoring during the infusion, which usually takes 2 to 5 hours.⁶⁶⁷ The initial rate is 0.01 mL/kg per minute, and if no side effects occur, it can be doubled at 15- to 30-minute intervals to a maximal rate of 0.08 mL/kg per minute. Rates above 5 mL/kg per hour (0.08 mL/kg per minute) are not recommended. Vital signs should be monitored frequently, and trained personnel should be available to treat adverse reactions. Adverse effects tend to be associated with rapid rates of infusion, patients with concurrent acute infections, previously untreated patients, or significant time elapse between infusions (>6-week intervals).

IGIV is contraindicated in patients who have had an anaphylactic reaction to IGIV or other blood products. It should be administered with great caution to patients who have IgG subclass deficiencies along with IgA deficiency or anti-IgA antibodies, or both.¹⁸³

In responsible, older patients receiving infusions without adverse effects, infusion by home self-administration can be accomplished with

considerable cost savings.^{52,390,659} However, in most cases, IGIV infusions are performed in the clinic setting or by a home infusion service.

A few investigators have given high concentrations (i.e., 9–12% solutions) infused rapidly during a period of 20 to 40 minutes, which may be tolerated by some patients.⁶¹⁵ However, it should not be done except by experienced personnel equipped to manage adverse reactions.

The brand, lot number, dose, premedication, and adverse reactions should be recorded. Cold solutions should be warmed to room temperature before administration.

Premedication, such as acetaminophen or diphenhydramine, is often given 30 minutes before infusions are started, particularly for the first infusion or for patients who have had prior reactions. Intravenous hydrocortisone (i.e., 5 to 6 mg/kg in children and 100 to 150 mg/kg in adults) or oral prednisone can be used for prevention of anticipated severe reactions.

Side effects of intravenous immunoglobulins. Certain brands of IVIG may cause more adverse reactions. In one study involving patients with Kawasaki disease, the two IGIVs used were equivalent therapeutically, but one had a 12-fold (2% vs. 25%) increase in side effects.⁵⁹⁰

Immediate reactions, such as headaches, shaking chills, nausea and vomiting, myalgias, or arthralgias that occur during or shortly after the infusions, are common occurrences.^{198,667,669} They may occur in as many as 10% of recipients, especially with a first infusion or in individuals with prior reactions.⁶⁶⁸ They can be treated by slowing or stopping the infusions and giving nonsteroidal antiinflammatory drugs, diphenhydramine, hydrocortisone, or other steroids. Occasionally, switching to a different product (usually one available as a solution) may alleviate the reactions.

Severe immediate reactions. Anaphylaxis, shortness of breath, hypotension, hypertension, and other immediate reactions are uncommon events. Because they rarely involve IgE antibodies, they are called anaphylactoid reactions, and they may be associated with cytokine release, complement activation, or vasoactive substance in the preparations.

Immediate reactions in immunoglobulin A–deficient patients. An occasional IgA-deficient patient exposed to blood, plasma, or any form of immunoglobulin may develop IgE anti-IgA antibodies, which can cause a reaction to the small amount of IgA in immunoglobulin.¹²⁵ IgG anti-IgA in high titers may cause a complement-mediated anaphylactic reaction.⁷⁴³ These reactions are rare, and testing patients for IgA deficiency before administration of IGIV is unnecessary. Patients with profound antibody deficiency do not develop anti-IgA antibodies. For the sensitized patient, the use of a low-IgA-content product or premedication is indicated. Although IgA deficiency is rare, patients with this condition should not be given IGIV unless it is absolutely indicated.

Aseptic meningitis. Headache is a common occurrence during or after IGIV infusions, but some patients develop severe headaches 6 to 24 hours after the infusion, sometimes associated with photophobia, stiff neck, and nausea.^{365,732} Several of these patients have had spinal taps that show cerebrospinal fluid (CSF) pleocytosis but negative viral and bacterial cultures. The symptoms usually resolve within 96 hours. This complication may recur despite changing brands of IGIV. Most occur when IGIV is used in large doses (e.g., 2 g/kg) for neurologic diseases. Individuals with a history of migraine may be more susceptible to aseptic meningitis.⁶²¹ These patients may tolerate slow infusions of subcutaneous immunoglobulin.^{572,671} Headaches and aseptic meningitis often can be avoided by premedication with steroids or with antimigraine medications.

Renal complications. Renal failure, usually temporary, has been reported with IGIV, particularly among patients with a history of renal disease.^{572,668} When such a problem is anticipated, IGIV should be given slowly at no more than 0.5 g/kg per day.⁶⁶⁸

Thrombotic complications. Several thrombotic events, including stroke, myocardial infarction, transient ischemic events, and central vein thrombosis, have occurred after IGIV infusions.⁶⁶⁸ These events may be associated with high doses and rapid infusion, particularly among patients with preexisting cardiovascular illness, obesity, immobility, or hematologic malignancy.^{42,668,779} However, further research is needed to establish the risk of thrombotic events in patients without these risk factors.⁴³

Rare side effects. Transient neutropenia, hemolytic anemia, acidosis, and symptoms of hyperviscosity occur rarely.^{117,668}

Transmission of pathogens, including hepatitis C, by intravenous immunoglobulin. Because IGIV is derived from human donors, a remote chance of transmission of viral or other pathogens exists. Tests of donors and the final products are performed, and newer testing for prions is in place but is not of proven reliability. No instance of HIV infection or Jakob-Creutzfeldt or new-variant Jakob-Creutzfeldt disease have been linked to the use of IGIV. Nonetheless, some patients with immunodeficiency receiving long-term IGIV therapy have developed progressive central nervous system problems.⁷⁹⁷

In the early 1990s, hepatitis C was transmitted by experimental IGIV lots.^{423,514} Some European preparations,^{86,87,421,768} and some commercially available US lots.^{143,612} Until the report of an outbreak of hepatitis C in 1994,¹⁴³ no US cases of hepatitis associated with a commercially available IVIG had been reported. Transmission occurred shortly after hepatitis C–seropositive donors were excluded from the donor pools used in the manufacture of IGIV.

A plausible explanation for the lack of transmission before this US Food and Drug Administration (FDA) policy was instituted is that the hepatitis C antibodies neutralized trace amounts of hepatitis C virus not eliminated during the fractionation. As of October 1994, 137 suspected cases were reported, 88 of which were confirmed.^{143,614} Of the 88 patients, 51 (58%) had primary immunodeficiencies, and 63% eventually became symptomatic.

Bjoro and associates⁸⁷ reported that immunocompromised patients had a severe and rapidly progressive course of hepatitis C infection and that responses to interferon (IFN) were poor. Razvi and colleagues⁵⁷³ did not confirm this finding in US patients. Newer manufacturing processes and more rigorous testing seemingly have eliminated the risk of hepatitis C transmission.

Intravenous immunoglobulin and intramuscular immunoglobulin inhibition of vaccine antibody responses. Live virus vaccines can have diminished immunogenicity when given shortly before or during the several months after receipt of immunoglobulin. Immunoglobulin administration inhibits the response to measles vaccine for a prolonged period, and inhibition of rubella vaccine also has been demonstrated. The interval between measles vaccine and immunoglobulin depends on the dose of immunoglobulin. The period of inhibition of response to varicella vaccine is not known, and the recommendation is to follow that for measles vaccine administration. Immunoglobulin does not impair responses to oral polio vaccine, oral rotavirus vaccine, or yellow fever vaccine.

In contrast to live virus vaccines, administration of immunoglobulin has not been demonstrated to cause significant inhibition of immune responses to inactivated vaccines and toxoids. Vaccines should be administered at sites different from those of IGIM. IGIV recipients should be immunized according to the recommended schedule for routine childhood immunization. The 2015 pediatric *Red Book* gives detailed recommendations.²³

Intravenous immunoglobulin in primary immunodeficiencies. Administration of IGIV is indicated for patients with profound primary antibody deficiency (i.e., quantitative and qualitative), for patients with combined immunodeficiencies, and for those with secondary immunodeficiency along with significant antibody deficiency (Box 246.1). Regular infusions of IGIV can keep patients with primary antibody immunodeficiencies free of infections for long periods or lessen the severity and frequency of chronic infections.⁵⁸¹

Patients with hereditary agammaglobulinemias, common variable immunodeficiency, and immunodeficiencies with hyper-IgM clearly benefit from replacement therapy. In combined antibody and cellular defects and in secondary antibody immunodeficiencies, administration of IVIG serves as an important ancillary treatment, but it does not correct the associated T-cell defect or underlying cause of the secondary immunodeficiency.

The recommended dose of IGIV is 400 to 600 mg/kg, usually given every 3 to 4 weeks.^{528,667} It should be given every 3 weeks if symptoms develop late in the period between monthly infusions. In general, the trough IgG level should be maintained at approximately 400 mg/dL higher than the pretreatment level, which normalizes the IgG level in most patients (e.g., 600–1000 mg/dL).

BOX 246.1 Immunodeficiencies for Which Human Immune Globulin May Be Beneficial**Antibody Deficiencies**

Congenital agammaglobulinemias
 Common variable immunodeficiency
 Immunodeficiencies with hyper-IgM
 Transient hypogammaglobulinemia of infancy (sometimes)
 IgG subclass deficiency with or without IgA deficiency (sometimes)
 Antibody deficiency with normal immunoglobulins

Combined Deficiencies

Severe combined immunodeficiencies (all types)
 Wiskott-Aldrich syndrome
 Ataxia-telangiectasia
 Short-limbed dwarfism
 X-linked lymphoproliferative syndrome

Secondary Immunodeficiencies

Malignant neoplasms with antibody deficiencies: multiple myeloma, chronic lymphocytic leukemia, and other cancers
 Protein-losing enteropathy with hypogammaglobulinemia
 Nephrotic syndrome with hypogammaglobulinemia
 Pediatric acquired immunodeficiency syndrome
 Intensive care patients: trauma, surgery, or shock
 After transplantation
 Burns
 Prematurity

Certain patients who experience continued infections may receive even higher doses (i.e., 600–800 mg/kg every 3 to 4 weeks).^{207,358} Patients receiving these larger doses may have less frequent sinopulmonary infections, improved pulmonary function, and decreased number of days of illness and hospitalization compared with patients receiving lower doses.⁶⁶⁷ Some investigators recommend giving even higher doses (i.e., keeping trough levels >800 mg/dL) in an effort to prevent pulmonary complications.^{207,358} Some patients with severe disease do not respond to higher doses or more frequent infusions because of permanent tissue damage or deep-seated chronic infection.

IGIV also is used in patients with antibody deficiency but with normal or almost normal immunoglobulin levels. These patients often need higher or more frequent doses of IGIV because their IgG catabolism is increased as a result of their high serum IgG levels. On rare occasions, IGIV is indicated for infants with transient hypogammaglobulinemia and persistent infection. IGIV also has been used in patients with IgG subclass deficiencies, but controlled studies demonstrating efficacy are lacking.^{85,390,643}

Special uses of intravenous immunoglobulin in antibody deficiencies. A syndrome of polymyositis or chronic encephalitis, or both, caused by persistent enteroviral infection in patients with agammaglobulinemia has been treated successfully with very high doses of IGIV containing specific antibody to the virus.^{470,565} However, some patients do not respond.¹⁸¹

A very high dose of IGIV (up to 2 g/kg per day) is used occasionally in patients with primary immunodeficiency who develop parvovirus B19 infection, autoimmune disease such as immune thrombocytopenic purpura, or persistent respiratory viral infection.⁶⁶⁷

Subcutaneous Human Immunoglobulin

An alternative to injection of IGIM or infusion of IGIV is slow subcutaneous infusion of immunoglobulin.^{4,81,80,244} This route is used extensively in Europe with a 16% preservative-free immunoglobulin. A preservative-free 16% product (Vivaglobin) was licensed in 2006 in the United States for subcutaneous use.⁵¹³ However, 10% to 12% solutions for IGIV also can be used safely.⁶⁷¹

These products usually are infused into the abdominal wall or thigh with a battery-operated portable infusion pump.^{80,244} The usual dose is 100 to 150 mg/kg per week, the same monthly dose as recommended for IGIV, given at a rate of 0.05 to 0.20 mL/kg per hour. Larger doses and more rapid infusions can be accomplished by using multiple injection sites. If a patient is beginning IGSC therapy and an immediate therapeutic level is sought, loading doses of IGIV at double the monthly maintenance dose can be given 1 week before the start of IGSC. Peak serum IgG levels after IGSC occur 48 to 96 hours after the infusion.

IGSC infusions, which can be self-administered, are well tolerated, safe, and preferred by some patients because the adverse reactions are considerably less.^{80,244,293} Premedication is rarely needed. They are more suitable than IGIV for home self-administration.^{243,244}

Stiehm and coworkers⁶⁷¹ used this route successfully in patients with poor intravenous access, aseptic meningitis after IGIV infusion, anaphylactic reactions after receiving IGIV infusion, or rapid gastrointestinal protein loss. IGSC has been used safely in IgA-deficient adults with frequent respiratory infections,²⁹³ during pregnancy,⁸² and in children.⁴

Rapid administration of IGSC has been achieved by using two pumps at four infusion sites and increasing the rate to 20 mL/h per pump, allowing the entire infusion to be completed in little more than an hour.²⁴⁴

Immunoglobulin Administration by Oral, Intrathecal, Aerosol, and Local Routes

Many types of antibody have been given by unusual routes with various degrees of success. None except intravitreal injection of monoclonal antibody is standard care.

Oral immunoglobulin. Breast milk is the ultimate oral passive immune agent with preventive benefit for newborns. Oral immunoglobulin administered to provide antimicrobial activity to the gastrointestinal tract mimics the action of antibody-rich colostrum and breast milk. In humans, little or no ingested immunoglobulin is absorbed intact into the systemic circulation.⁴⁴ Some oral immunoglobulin traverses the entire gastrointestinal tract undigested, particularly in premature infants.⁷⁵ Oral immunoglobulin may neutralize microorganisms, inhibit colonization, and prevent microbial attachment to the gastrointestinal mucosa.

Rotavirus infection. Barnes and colleagues⁷⁰ fed human immunoglobulin or placebo for 7 days to premature infants in a nursery in which rotavirus was endemic. Rotavirus-associated diarrhea developed in 6 of 11 babies given placebo and in 1 of 14 given oral immunoglobulin. Oral administration of immunoglobulin in low-birth-weight infants may be a useful strategy in treating rotavirus infections, but further clinical trials are needed to assess efficacy.⁵³⁵

Lososky and coworkers⁴³⁴ administered oral human immunoglobulin to two children with severe combined immunodeficiency and chronic rotavirus infection and demonstrated a decrease in the amount of free rotavirus excretion and survival of the immunoglobulin through the gastrointestinal tract. Kanfer and associates³⁶¹ used oral human immunoglobulin to treat rotavirus infection that occurred after bone marrow transplantation. In 2015, Williams reported the use of enteral immunoglobulin in four pediatric stem cell transplant recipients with good results.⁷⁶⁷

Bovine hyperimmune colostrum immunoglobulin enriched in rotavirus antibodies (from immunized cows) also has been used in the prevention of rotavirus infection. Davidson and colleagues¹⁸⁶ prevented rotavirus infection in 55 children admitted to an Australian hospital by administering a 10-day course of bovine colostrum; nine of 65 control children became infected.

Turner and Kelsey⁷¹⁶ added at least 360 mL of cow colostrum to the formula of 31 term infants 3 to 7 months of age for an average of 101 days (range, 16–202 days). Rotavirus infections occurred in 11 (35%) of the colostrum-fed group and 14 (42%) of the control group, an insignificant difference, but symptomatic infection occurred in 1 (3%) of the infants receiving colostrum and 6 (18%) of the controls.

This product also has been used in two studies of the treatment of rotavirus diarrhea in Bangladesh.^{481,609} In both studies, less diarrhea, fewer days of illness, less stool output, and more rapid clearance of

rotavirus from the stool occurred. Guarino and coworkers²⁸⁶ used oral human immunoglobulin (300 mg/kg) as a single dose and observed more rapid recovery from rotavirus diarrhea. Oral immunoglobulin is a promising but unproved agent for the prevention and treatment of rotavirus infection.

Necrotizing enterocolitis. Eibl and colleagues²⁰⁶ were able to prevent necrotizing enterocolitis in all 90 infants given oral immunoglobulin rich in serum IgA. Six cases occurred among 91 control infants. Rubaltelli and colleagues⁵⁹² in Italy achieved similar results with oral monomeric IgG.

Cryptosporidial infection. Bovine colostrum was used successfully to treat cryptosporidial diarrhea in HIV infection.⁶³⁴ Borowitz and Saulsbury¹⁰² used oral immunoglobulin successfully to treat cryptosporidial infection in a child with acute leukemia.

Other diarrheas. Oral human immunoglobulin has been used after bone marrow transplantation and lung transplantation to prevent the development of viral gastroenteritis^{239,361} and to treat nonspecific diarrhea in immunodeficient patients.⁴⁷³ Commercial products from bovine colostrum are available in Sweden and India.^{235,548} Considerable experimental study findings in veterinarian medicine are available for other oral immunoglobulins.

Aerosolized and intratracheal immunoglobulin. Aerosolized and intratracheal immunoglobulin has been used with encouraging results in experimental models of pneumonia caused by RSV, pneumococci, staphylococci, *Yersinia pestis*, and parainfluenza and influenza viruses.^{270,314,531,569,570,586} Aerosolized monoclonal antibodies also are being studied for specific infections, bioterrorist toxins (e.g., anthrax, ricin), and lung immunomodulation.^{218,415,559,738}

Rimensberger and colleagues⁵⁸² conducted a placebo-controlled trial of aerosolized human immunoglobulin (not RSV-IVIG) in the treatment of RSV infection. No significant benefit was found, but the treatment was well tolerated.

Heikkinen and coworkers³⁰⁶ used an IgA-enriched human immunoglobulin as a nasal spray twice daily for 8 weeks to reduce respiratory infections in children between 1 and 4 years of age attending childcare. A 42% reduction was achieved among the 19 children receiving the immunoglobulin compared with the 20 children in the placebo group. The study authors suggested that this treatment also could decrease the incidence of otitis media.

Intrathecal immunoglobulin. Human immunoglobulin has been used intrathecally for the treatment of viral encephalomyelitis in patients with antibody deficiency.²¹⁵ Monoclonal antibodies occasionally are given intrathecally in cancer therapy.⁶⁶⁵ The use of antitoxin intrathecally in tetanus is discussed in the section on [tetanus](#).

Other administration routes. Local application of antibody has been used in the prevention and treatment of surgical and traumatic wounds.^{373,558} Injections of the monoclonal antibody bevacizumab (Lucentis) into the vitrea to treat macular degeneration are being tested.¹⁷⁶ Inner ear injection of infliximab, a tumor necrosis factor (TNF) monoclonal antibody, has been used in autoimmune neurosensory hearing loss.⁷³⁰ Intraarticular immunoglobulin had no clinical benefit for patients with rheumatoid arthritis.⁵⁷

Immunoglobulin in Secondary Immunodeficiencies

Many chronically ill patients have a primary illness that results in immunosuppression and increased susceptibility to infection. These secondary immunodeficiencies are considerably more common than primary immunodeficiency and are particularly common developments in hospitalized patients. Although most patients have cellular (T-cell) deficiencies, some have antibody deficiencies that are isolated or combined with other immune defects. These patients may have low immunoglobulin levels, poor antibody responses to antigenic challenge, low levels of natural antibodies that may result from loss of immunoglobulin, loss of immune cells, or the toxic effect of therapy or infection on the immune system. [Box 246.1](#) lists diseases and conditions in which secondary antibody immunodeficiency can occur.

Laboratory criteria that support the use of IGIV include significant hypogammaglobulinemia (serum IgG <200 mg/dL or total immunoglobulin [IgG + IgM + IgA] <400 mg/dL), absent or unexpectedly low titers of natural antibodies, absent or poor response to antigenic challenge

(i.e., tetanus or pneumococcal vaccines), and lack of an antibody response to the infecting organism.⁶⁶⁹ Some of the more common secondary immunodeficiencies with antibody defects are discussed in the following sections.

Hematologic and Oncologic Diseases

Antibody deficiencies can occur with multiple myeloma, chronic lymphocytic leukemia, lymphoma, and advanced cancer, aggravated by the immunosuppressive agents used in their therapy. A double-blind multicenter study concluded that the prophylactic infusion of 400 mg/kg of IGIV every 3 weeks reduced the incidence of bacterial infections in patients with chronic lymphocytic leukemia.¹⁷² The treatment group had fewer infections with *Streptococcus pneumoniae* and *Haemophilus influenzae*, but no difference was observed in infections caused by other gram-negative bacteria, fungi, or viruses.

This beneficial effect has been confirmed in subsequent studies,^{177,240,289} and although concern has been raised about its cost-effectiveness,⁷⁵³ IGIV has been shown to reduce the incidence of infections in patients with multiple myeloma¹⁵⁷ and in those receiving chemotherapy for lung cancer.⁶¹⁷ However, Blombery and colleagues⁹⁰ found no benefit in the routine use of peritransplantation IVIG to reduce infectious complications in patients with multiple myeloma undergoing autologous hematopoietic stem cell transplantation.

Protein-Losing States: Enteropathy, Nephrotic Syndrome, and Plastic Bronchitis

In some pediatric patients, antibody deficiency results from massive proteinuria (i.e., nephrosis), diarrhea (i.e., protein-losing enteropathy), or loss into the lung (i.e., plastic bronchitis) associated with accelerated IgG loss. Most of these patients have minimal trouble with recurrent infection, probably because antibody synthesis is intact and most likely accelerated. However, if the loss of IgG greatly exceeds synthetic capacity, symptomatic severe hypogammaglobulinemia may result. IGIV infusions can be used diagnostically in such cases. A large intravenous infusion, followed by serial measurements of serum IgG levels, can document an accelerated IgG half-life (i.e., <10 days).

These patients are candidates for IGIV therapy if they have recurrent infections or very low IgG levels (e.g., <200 mg/dL). Administration of large and repeated doses of IGIV is necessary. Occasionally, antibody infusions help to control the severe diarrhea of protein-losing enteropathy.¹³³ IGSC has been used in this situation because its delayed release into the circulation can generate higher long-term IgG levels than can be achieved with an equivalent IGIV monthly dose.⁶⁷¹

Intensive Care Patients: Trauma, Surgery, and Septic Shock

Patients undergoing severe stress associated with trauma or extensive surgery have profound exposure and susceptibility to infection and a spectrum of immune deficiencies, including cutaneous anergy, leukocyte dysfunction, hypogammaglobulinemia, and transiently impaired antibody synthesis.^{265,492,771} Bowel stasis and hypotension may promote gram-negative sepsis or endotoxemia, or both, along with the development of severe and often irreversible shock.

Early studies by Ziegler and associates⁷⁹⁶ and Baumgartner and colleagues⁷⁴ suggested that when antisera to a mutant J5 *Escherichia coli* endotoxin with anti-lipid A activity is used in bacteremic or surgical intensive care unit (ICU) patients, the incidence and severity of severe shock could be reduced. However, Calandra and colleagues,¹³⁰ used a human IGIV to J5 *E. coli* in 71 patients with gram-negative infections and shock and could not confirm their results. No differences were found in mortality rates, onset of time to shock, and complications.

Just and coworkers³⁵⁵ administered IGIV and antibiotics to 50 patients in the ICU thought to have infection and compared their outcomes with 54 control patients who received antibiotics alone. Although no difference in survival occurred, they found a trend indicating that the IGIV-antibiotic group had a shortened stay in the ICU, a shorter period in which respiratory therapy was required, improved renal function, and a favorable effect on infection. Ferrara and colleagues²²⁷ reported that IGIV was a viable adjunct treatment option for certain cases of drug-resistant bacterial infections, and there was a clear survival

advantage with the use of IGIV in adult sepsis syndromes by suppressing inflammation.

Rodriquez and colleagues⁵⁸⁸ gave an IgM-enriched IGIV or albumin to 56 patients with sepsis undergoing abdominal surgery and found a reduction of sepsis from 55% to 25%. Another multicenter study of 352 postsurgical patients confirmed the observation that standard IGIV (400 mg/kg at weekly intervals) reduced the incidence of infections and shortened the stay in the ICU in contrast to patients treated with placebo or hyperimmune core-lipopolysaccharide immunoglobulin.³³²

Werdan⁷⁵⁹ reviewed the use of IGIV in sepsis and suggested certain specific subgroups could benefit (e.g., postoperative sepsis, septic shock with endotoxemia, sepsis with neutropenia). Although certain subgroups may benefit from the use of IGIV for sepsis, there is a need for further clinical trials to make a recommendation for use.^{15,629,656} Tagami and colleagues reviewed the role of IGIV as an adjunctive treatment in 1324 patients with pneumonia and septic shock from July 2010 through March 2013, and found no reduction in mortality rates.⁶⁹⁵ A single-institution study from Egypt suggested that IGIV was beneficial in children younger than 2 years of age in the ICU who had sepsis.²⁰⁹ Studies of IGIV in trauma patients requiring surgery^{188,197,263,694} and in patients with head trauma⁷⁷¹ have shown questionable efficacy.

Monoclonal antibodies to endotoxin have been tested in clinical trials of patients in septic shock, but none had proven efficacy.^{499,760,795} Monoclonal antibody to TNF- α also has shown no efficacy in the treatment of adults with septic shock.^{3,169} Monoclonal antibodies to interleukin-6 (IL-6) or IL-1 receptor likewise have not been effective in the treatment of shock.²⁴⁶

Prematurity

All premature infants have low levels of maternally derived IgG at birth, and levels approaching 100 mg/dL develop in the first months of life in most.⁶⁵ The IgG levels may be further depressed by pulmonary disease (with transudation into the lungs), fever and stress (with increased IgG catabolism), and multiple blood sampling.⁵¹⁹ Their sluggish antibody responses, concurrent IgM and IgA deficiencies, and immature complement, phagocytic, and T-cell systems render low-birth-weight infants extraordinarily susceptible to development of infection.⁴²⁶

Attempts to decrease the incidence of infections in premature infants by using periodic immunoglobulin injections began in the 1960s. Four controlled studies enrolling a total of 363 infants used immunoglobulin doses of 80 to 240 mg/kg per month during their stay in the nursery (two studies), for 4 months, and for 1 year.^{20,171,194,663} In two studies, a slight decrease in the number and severity of infections was observed, but there was no difference in survival. These mixed results suggest that immunoglobulin at the doses used had no prophylactic value for these patients.

In the past few decades, the increasing rate of survival of premature infants and the availability of IGIV have reawakened interest in the use of antibody to prevent infections in premature infants. An initial double-blind clinical trial by Baker and colleagues⁵⁸ suggested that IGIV at a dose of 0.5 g/kg at frequent intervals in the first weeks of life significantly reduced the frequency of sepsis, particularly that caused by *Staphylococcus epidermidis*. Subsequent studies, however, did not show a clear benefit.

Meta-analyses of prospective, randomized, placebo-controlled prevention studies (representing 5000 infants) were performed by Jensen and Pollock^{343,344} and Ohlsson and Lacy.^{520,522,523} These studies had different entry criteria, doses, and brands of IGIV, but most infants weighed less than 2000 g, were given IGIV therapy within the first week of life, and received doses of at least 400 mg/kg per month; culture-proven sepsis was used as an end point. Overall, a slight reduction (3%) was seen in the incidence of sepsis, but there were no differences in mortality rates, length of stay, or other complications of prematurity, such as necrotizing enterocolitis, bronchopulmonary dysplasia, and intraventricular hemorrhage. The International Neonatal Immunotherapy Study Collaborative Group concluded that IGIV had no effect on outcomes of suspected or proven neonatal sepsis.²⁸⁴

Shamin and coworkers⁶²⁷ gave sufficient IGIV for 6 months to 15 of 30 matched premature infants with severe bronchopulmonary dysplasia

to maintain their IgG levels above 400 mg/dL, whereas the untreated infants had levels below 200 mg/dL. The number of infections, notably pneumonia, was significantly reduced in the IGIV group (i.e., 5 episodes of pneumonia and 4 other infections) in contrast to the control group (i.e., 15 episodes of pneumonia and 12 other infections). In 2011, a large collaborative study of 113 hospitals in nine countries evaluated the use of IGIV in neonatal sepsis and found no effect on the outcome of suspected or proven neonatal sepsis.²⁸⁴

The evidence still supports the 1990 National Institutes of Health (NIH) consensus statement that IGIV should not be given routinely to infants of low birth weight⁵⁰¹ but that it may be of value in selected premature infants at high risk for infection. IGIV is sometimes beneficial for premature infants with a history of serious infections and underlying lung disease; most have hypogammaglobulinemia and should be regarded as having transient hypogammaglobulinemia of infancy.

Hyperimmune IGIV, or monoclonal antibodies enriched in antibodies against specific microbial antigens (e.g., *Staphylococcus aureus*), may be beneficial for certain high-risk newborn and premature infants. Two large, multicenter, double-blind clinical trials of *S. aureus* hyperimmune human immunoglobulins enrolled infants with very low birth weights. One (Altastaph) used immunoglobulin from donors immunized with a staphylococcal vaccine against serotypes 5 and 8.^{78,450} The other (Veronate) used immunoglobulin from donors with a high titer to C1fA, a staphylococcal fibrinogen-binding protein.^{91,135,189,367} Neither trial showed a significantly decreased severity or incidence of staphylococcal infections. The anti-lipoteichoic acid monoclonal antibody, pagibaximab, demonstrated safety and tolerability, but it did not reduce overall rates of neonatal sepsis.⁵⁴⁶

Transplantation

Conditioning regimens to eliminate or reduce the host's hematopoietic and immune systems before transplantation (i.e., bone marrow and solid organ) render these patients extremely susceptible to infection, particularly cytomegalovirus (CMV) infections.⁷¹⁷ IGIV and CMV intravenous immunoglobulin (CMV-IGIV) have been used to prevent infection and to modify graft-versus-host disease and prevent solid organ transplant rejection.

Early studies of IGIV therapy after allogeneic bone marrow transplantation were modestly successful in preventing infections, decreasing graft-versus-host reaction, and increasing survival rates.^{6,73,173,271,687,685,686} This effect was less dramatic when CMV infection was controlled by ganciclovir and screening of blood products.²⁸⁸ Two more multicenter studies showed only a modest or no effect on modifying acute graft-versus-host reactions or mortality rates.^{175,773} In single-center studies, CMV-IGIV was of no benefit in CMV-positive lung transplant recipients³⁹⁹ or liver transplant recipients.²⁷⁶

IGIV is beneficial for adult kidney transplant recipients with high titers of human leukocyte antigen (HLA) antibodies, resulting in a shorter time to transplantation, reduced HLA antibody titers, and improved allograft survival rates.^{350,351} The use of IGIV together with other immunomodulatory therapies, such as anti-CD 20, are being studied to reduce infectious complications in renal transplant recipients.⁷⁴¹

Burns

Bacterial sepsis, particularly *Pseudomonas* spp. and *E. coli* sepsis, is the leading cause of death of the 300,000 patients hospitalized annually in the United States for burns.^{491,492} The protein loss in these patients induces hypogammaglobulinemia in proportion to the severity of the burn. High-dose IGIV prolongs survival in experimentally burned mice infected with *Pseudomonas* spp., and preliminary studies of hyperimmune immunoglobulin and plasma administered to human burn patients were encouraging, but proof of efficacy is lacking^{372,560,681} (discussed later).

Human Immunodeficiency Virus Infection

Chapter 192B discusses HIV infection.

Intravenous Immune Globulin in Immunoregulatory and Neurologic Disorders

High-dose IGIV has immunosuppressive and antiinflammatory effects that render it a valuable agent in the treatment of several autoimmune,

BOX 246.2 Likely Benefit of Intravenous Immunoglobulin for Autoimmune, Inflammatory, and Neurologic Diseases

Proven Benefit^a

Kawasaki disease
Graves ophthalmopathy
Immune thrombocytopenic purpura (e.g., idiopathic)
Dermatomyositis
After bone marrow transplantation
Neurologic diseases
 Guillain-Barré syndrome
 Chronic inflammatory demyelinating polyneuropathy
 Multifocal motor neuropathy
 Demyelinating neuropathy with IgM gammopathy

Probable Benefit^b

Toxic shock syndrome
Postinfectious thrombocytopenic purpura
Neonatal isoimmune or autoimmune thrombocytopenic purpura
Neonatal isoimmune or autoimmune hemolytic anemia
Autoimmune or isoimmune neutropenia
Autoimmune hemolytic anemia
Toxic epidermal necrolysis
Prevention of antibody-mediated kidney transplant rejection
Autoimmune uveitis
Neurologic diseases
 Polymyositis
 Lambert-Eaton myasthenia syndrome
 Myasthenia gravis
 Stiff man syndrome
 Relapsing-remitting multiple sclerosis

Possible Benefit^c

Anticardiolipin antibody syndrome
Coagulopathy with factor VIII inhibitor
Bullous pemphigoid and other blistering skin diseases
Churg-Strauss vasculitis
Vasculitis with antineutrophil cytoplasmic antibodies
Other vasculitides
Stevens-Johnson syndrome
Severe rheumatoid arthritis
Systemic lupus erythematosus
Autoimmune diabetes mellitus
Posttransfusion purpura
Prevention of allograft rejection in high-risk patients with solid organ transplants

Recurrent spontaneous abortion
Cardiomyopathy
Severe, persistent, high-dose steroid-dependent asthma
Chronic urticaria
Autoimmune liver disease
Delayed pressure urticaria
Neurologic diseases
 Multiple sclerosis
 Rasmussen syndrome
 Intractable childhood epilepsy
 Demyelinating neuropathy with anti-GAD antibodies
 Acute disseminated encephalomyelitis
 Cerebral infarction with antiphospholipid antibodies
 HTLV-1-associated myelopathy
 Lumbosacral or brachial plexitis
 Paraproteinemic neuropathy
 Opsoclonus-myoclonus syndrome
 Postinfectious cerebellar ataxia
 Acute idiopathic dysautonomia

Unproven or No Benefit^d

Non-steroid-dependent asthma
Atopic dermatitis
Epidermolysis bullosa acquisita
Hemolytic-uremic syndrome
Thrombotic thrombocytopenic purpura
Pure red cell or white cell aplasia
Acquired von Willebrand disease
Chronic fatigue syndrome
Infantile autism
Acute myocarditis
Chronic graft-versus-host disease
Inflammatory bowel disease
Neurologic diseases
 Inclusion body myositis
 Amyotrophic lateral sclerosis
 Paraneoplastic cerebellar degeneration, sensory neuropathy, encephalitis syndrome (e.g., POEMS)
 Sensory neuropathy
 Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS)
 Alzheimer disease

Levels of benefits:

^aControlled studies demonstrate efficacy.

^bSeveral case reports or uncontrolled series are convincing.

^cPreliminary studies are encouraging but incomplete.

^dPreliminary studies are limited, equivocal, or negative.

HTLV, Human T-lymphotropic virus; IgM, immunoglobulin M; POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes.

inflammatory, and neurologic disorders (Box 246.2).^{201,528} A consensus committee evaluated these uses in terms of likely effectiveness.⁵²⁸ High-dose IGIV (1 to 2 g/kg) may work by one or more of the following mechanisms^{64,201,645,698}:

1. IGIV can decrease the high levels for a pathogenic antibody (e.g., in myasthenia gravis or idiopathic thrombocytopenic purpura) by accelerating IgG catabolism. IGIV increases IgG levels acutely and increases its catabolism, decreasing pathogenic antibodies present in high concentrations. It also saturates the FcRn receptor, inhibiting the recirculation of IgG molecules.⁷⁸⁷ IGIV inhibits antibody synthesis by having a direct effect on proliferating B cells, possibly through activation of the FcR2 receptor.⁶⁰⁵
2. IGIV contains antiidiotypic antibodies that can combine with autoimmune antibodies and remove them rapidly from the circulation, which may be a mechanism by which IGIV reduces anti-HLA antibodies in transplant recipients.
3. IGIV binds to Fc receptors on reticuloendothelial cells and causes an Fc receptor blockade, reducing the destruction of antibody-coated cells in the spleen or liver. It is a mechanism for the rapid response to IGIV observed in patients with immune thrombocytopenic purpura. Dimeric IGIV can be particularly effective in causing FcR blockade.
4. IGIV combines with other surface receptors to inhibit cellular activation. For example, in toxic epidermal necrolysis, IGIV prevents

FAS-mediated cell death of keratinocytes by blocking the FAS receptor.⁷³⁴

5. IGIV may promote solubilization and clearance of pathologic immune complexes, such as may be present in lupus nephritis.
6. IGIV downregulates T-cell immune activation by decreasing inflammatory cytokine release or action. In Kawasaki disease, an immediate damping of the cytokine storm occurs after IGIV administration.
7. IGIV antibodies neutralize bacterial superantigens and prevent them from activating T cells. This is the probable mechanism for its beneficial effect in toxic shock syndrome (TSS).^{662,698}
8. IGIV combines with complement components to prevent complement-mediated tissue injury. An example is inhibition of complement-mediated myocyte damage in dermatomyositis.
9. IGIV neutralizes virus or bacterial antigens or toxins that may trigger or cause the disease. An example is the neutralization of bacterial products in hemolytic uremic syndrome.
10. IGIV contains substances such as soluble HLA antigens and soluble cytokine receptors that can inhibit immune responses.

The illnesses for which IGIV may be of benefit often have unknown causes and are refractory to standard treatment, somewhat responsive to steroids, and associated with local or generalized immune activation with fever, inflammatory cells, and cytokine release.⁵¹⁶ Large doses of IGIV (e.g., usually 1 to 2 g/kg per day) are necessary and may need to be repeated. IGIV preparations are not always equivalent in action. Tsai and associates⁷¹⁴ found that certain brands of IGIV were less effective in Kawasaki disease than others.

If a favorable response does not occur immediately or within a few weeks, it probably will not occur later. Proof of efficacy requires a double-blind study (e.g., one conducted for Kawasaki disease) or dramatic reversal of progressive severe disease (e.g., some cases of TSS). The use of IGIV in Kawasaki disease is covered in Chapter 77.

Monoclonal Antibodies

Monoclonal antibodies specific for a single antigenic epitope have been available for laboratory use for several decades and are used increasingly as therapeutic agents. The first monoclonal antibody, which was licensed in 1984, was a murine antilymphocyte antibody (i.e., anti-CD3 [OKT3]) used for immunosuppression in transplant recipients. Since then, numerous other monoclonal antibodies have been licensed for treatment, and many others are being studied in the United States and abroad.¹²⁷

Nomenclature and Structure

The generic names of therapeutic monoclonal antibodies have been codified as summarized in Table 246.2.¹²⁷ All end in *-mab* or *-nab*. Preceding this ending is a one- or two-letter prefix that denotes the animal from which it has been produced (e.g., *o* for mouse, as in *muromonab*; *u* for human, as in *adalimumab*).

Two types of monoclonal antibodies contain both human and murine components. Chimeric monoclonal antibodies, designated with the syllable *xi*, contain the Fab portion of a murine immunoglobulin and the Fc portion of human immunoglobulin, usually an IgG1 molecule (e.g., *rituximab*). Humanized monoclonal antibodies, designated with the syllable *zu*, have only the antibody-combining site of a murine immunoglobulin (i.e., complementary determinant region), and the remainder of the molecule is a human IgG1 molecule (e.g., *omalizumab*). Chimeric and humanized antibodies are less antigenic and have a longer half-life than mouse monoclonal antibodies and usually are preferred.

One completely human monoclonal antibody is derived from isolated and recombined human light and heavy chains (i.e., *adalimumab*).

The final prefix before the source prefix designates the disease for which the antibody is used (e.g., *vir* for viral disease, *lim* for immune modulation, *tu* for cancer). Examples include *palivizumab*, *omalizumab*, and *trastuzumab*. Sometimes the last consonant is dropped for the sake of pronunciation. The beginning of the generic name is left to the manufacturer, as is the trade name.

Uses of monoclonal antibodies. Therapeutic monoclonal antibodies are licensed for graft rejection, cancer, autoimmunity (e.g., rheumatoid arthritis, inflammatory bowel disease, immune cytopenias), thrombosis, infectious disease, multiple sclerosis, asthma and allergy, and macular

degeneration. Like many new drugs, monoclonal antibodies also are used for disorders other than those for which they are licensed.

Only one of these antibodies, *palivizumab* (Synagis), which is directed against RSV, is used in infectious diseases for the prevention of RSV infection in high-risk infants (see [Respiratory Syncytial Virus](#)).³⁵ However, monoclonal antibodies to microbial antigens and inflammatory mediators will play an important role in tomorrow's battle with infectious pathogens. For example, monoclonal antibodies to anthrax toxin, staphylococcal antigens, and HIV antigens and coreceptors are being studied.

PASSIVE IMMUNITY IN BACTERIAL DISEASES

Antibodies have been used for a century for the prevention and treatment of infectious diseases (Table 246.3). In bacterial disease, antibodies neutralize toxins, facilitate opsonization, and with complement, promote bacteriolysis. In viral disease, antibodies block viral entry into uninfected cells, promote antibody-directed cell-mediated cytotoxicity by natural killer cells, and neutralize virus alone or with the participation of complement.

Before the use of antibiotics, antibodies were the only specific agents for the treatment of certain infections. Although this role has been supplanted largely by antibiotics, antibody still has a crucial role in the treatment of certain infectious diseases (see [Box 246.2](#)). The remainder of this chapter discusses the roles of antibody in the prevention and treatment of bacterial and viral diseases. Other reviews are available.^{138,137,419}

Anthrax

Anthrax is a rare but serious infectious disease, predominantly of ruminant animals, caused by an aerobic gram-positive rod, *Bacillus anthracis*.^{153,439,440} Humans can be infected through the skin (i.e., cutaneous anthrax), by ingestion (i.e., gastrointestinal anthrax), or by inhaling the spores (i.e., inhalation anthrax).⁴⁴⁰ Inhalation anthrax results from prolonged exposure to animal hides or carcasses and infected soil or rarely from deliberate spore exposure in the bioterrorism setting, as occurred in 2001, when anthrax spores were sent through the US mail.^{345,439}

After inhalation, the spores are ingested by alveolar phagocytic cells and transported to regional nodes, where they germinate and release exotoxins (i.e., lethal toxin and edema toxins), which damage cell membranes, increase capillary permeability, initiate pulmonary changes, and ultimately lead to shock and cardiovascular collapse.

A vaccine is available for individuals at high risk for exposure and the military. It is effective against cutaneous anthrax but has unproven efficacy against inhalation anthrax.³⁴⁴ Other vaccines are being developed.¹⁰⁸

Before the antibiotic era and as early as 1903, anthrax antitoxin (usually equine) was used in the treatment of anthrax.^{265,388} An antitoxin would be of value in a bioterrorism attack before exposure and after exposure. The Centers for Disease Control and Prevention (CDC) and the NIH are collecting plasma units from military recruits and volunteers immunized with the anthrax vaccine²¹⁴ to develop a human high-titer IGIV from these donors.^{154,764}

Several monoclonal antibodies against anthrax antigens have been produced.^{111,160,326,445,460,487,685,749} The best studied is a human monoclonal antibody 5H3 (i.e., *raxibacumab*).¹⁶⁰ *Raxibacumab* is a human IgG1 λ monoclonal antibody directed against a component of the anthrax toxin. It was shown to be safe and well tolerated intravenously and intramuscularly in human volunteers and provided good antibody titers with a half-life of 15 to 19 days.⁶⁸⁴ Two animal efficacy studies demonstrated that a single dose of *raxibacumab* given in the absence of antibiotics improved survival rates up to 64%, even when administered after animals were already showing clinical symptoms of inhalation anthrax.⁴⁷⁷ In 2009, 20,000 doses of *raxibacumab* were delivered to the US Strategic National Stockpile, and later that year, an additional 45,000 doses were made available. In 2012, the FDA approved *raxibacumab* as treatment in combination with antibacterial drugs for inhalation anthrax. *Raxibacumab* was also approved for prevention of inhalation anthrax when other therapies are not available or appropriate. *Raxibacumab* is supplied by the US government.

Administration of anthrax immunoglobulin (AIG) to a 44-year-old man with naturally occurring inhalation anthrax demonstrated a

subsequent decrease in plasma and pleural fluid lethal factor and an increase in antiprotective antigen IgG.⁷⁴⁷

Recommendations

In addition to raxibacumab, a limited supply of immune plasma is stockpiled by the US army and is available through an emergency investigational new drug (IND) protocol. This supply would be used in conjunction with antibiotics and with vaccine, the latter to provide immunity after metabolism of the antibody. Immunotherapeutics should be considered for patients with severe systemic illness or lack of clinical response to standard therapy.^{105,666}

Botulism, Botulinum Antitoxin, and Botulinum Immunoglobulin

Botulism, a severe paralytic poisoning, results from ingestion or absorption of neurotoxins or spores from *Clostridium botulinum*. Several

clinical variants are recognized: food poisoning from ingestion of contaminated canned food, wound botulism from a contaminated local infection, inhalation botulism among individuals working with the toxin or in bioterrorism,⁴⁸ infant botulism from ingestion of *C. botulinum* spores, and adult-type infant botulism in adults with preexisting gastrointestinal disease. In the last two types, ingested spores multiply in the gastrointestinal tract and produce toxin, which after absorption results in a paralytic disorder.^{79,139} Botulism resulting from cosmetic use of an unapproved botulinum toxin A has been reported.^{162,660}

Seven immunologic types of *C. botulinum*, designated A through G, have been identified; each elaborates an immunologically distinct toxin. Most human botulism results from the ingestion of toxins A, B, and E; toxin E is usually associated with fish and marine mammal products.^{392,393,630}

Japanese studies, reviewed by Dolman and Iida,¹⁹⁵ indicate that antitoxin therapy is effective for type E botulism. The mortality rate associated with type E botulism was 49% for 135 untreated cases and 3.5% for 85 antitoxin-treated cases.

Tacket and associates⁶⁹² observed that 46 patients who had type A foodborne botulism and who received trivalent antitoxin had a lower mortality rate (27%) than 13 patients who did not receive antitoxin (46%). Early antitoxin administration resulted in a shorter clinical course.

Toxin found in the blood long after the appearance of clinical symptoms or the ingestion of toxin gives theoretical support to the use of antitoxin to prevent further binding of toxin to tissue. Some antitoxin remains in the circulation for more than 30 days, indicating that a single initial dose is adequate therapy.

Equine antitoxins to *C. botulinum* types A, B, and E are the primary antitoxins available in the United States. The decision to use antitoxin is complicated by its unknown efficacy and its side effects, but approximately 80% of patients with ingestion-type botulism receive antitoxin.⁶³⁰ Chapter 147 provides more information on infant botulism.

Recommendations

All forms of botulism except for infant botulism are treated with a heptavalent botulinum antitoxin (HBAT) that replaced the previously available bivalent antitoxin AB and monovalent antitoxin E. HBAT contains equine-derived antibody to the seven known botulinum toxin types (i.e., A–G). Administration of HBAT requires an FDA IND treatment protocol. Suspected cases should be immediately reported to local and state health authorities, and further guidance is available from the CDC's 24-hour hotline (770-488-7100).¹⁴⁷ Additional information regarding the CDC botulism treatment program is available on the CDC website (<http://www.bt.cdc.gov/agent/botulism>). Administration of HBAT should occur only after testing for sensitivity to horse serum because of the risk for hypersensitivity reactions, including anaphylaxis and serum sickness.^{23,24,139,630}

Antitoxin can be given prophylactically to individuals known to have ingested contaminated food. The risk of development of serum reactions (about 10%) must be weighed against the risk of contracting the disease.

A 5-year, placebo-controlled, double-blind trial of human botulinum intravenous immunoglobulin (BIG) for the treatment of infant botulism showed a significant reduction in hospital days, mechanical ventilation, tube feedings, and days of hospitalization in the BIG recipients, with considerable cost savings and minimal adverse events.⁴⁹ Three retrospective studies demonstrated similar decreases in the previously described interventions.^{156,708,715,720} BIG should be started as soon as possible after the illness is suspected, and it is available through the California Infant Botulism Treatment and Prevention Program (<http://www.infantbotulism.org/>).

Other Clostridial Infections

Clostridium difficile Infections

Clostridium difficile is a ubiquitous, spore-forming anaerobe often involved in antibiotic-associated diarrhea and pseudomembranous colitis.^{24,25} Severity of the disease can range from an asymptomatic carrier state to fulminant colitis with toxic megacolon. Toxic strains of *C. difficile* release two antigenically distinct toxins, both of which have potent cytotoxic and inflammatory properties.¹⁶⁸ Infection usually leads to an antibody response to the toxins, and most individuals older than 2 years have the antibodies; *C. difficile* antibodies therefore are present in IGIV preparations.⁶⁰²

High levels of IgG antibodies acquired after colonization are associated with the asymptomatic carrier state; individuals who have persistent diarrhea have significantly lower serum IgG but not IgA to toxin A.⁴¹³ Several patients have been identified with relapsing symptomatic disease who have low IgG antibody levels to toxin A.^{302,422} Some of these patients had low levels of IgG⁴²² or IgG1 subclass deficiency³⁰² and were treated successfully with IGIV. Since the initial use of IGIV to treat patients with recurrent disease, many studies have demonstrated that IGIV contains neutralizing antibodies to toxin A and toxin B.

IGIV treatment of individuals with severe disease, including sepsis, abdominal distention with ileus, and toxic megacolon, has been reported.³⁵³ The development of an immunoglobulin preparation derived from volunteers immunized with *C. difficile* toxoid vaccine has the potential to provide higher-titer specific antibodies for treatment of recurrent or refractory *C. difficile* infection. The mechanism thought to be responsible for the protective effect of IGIV is binding and neutralization of toxin A by IgG anti-toxin A antibodies.²

Oral administration of a bovine IgG concentrate was effective in preventing diarrhea and death in hamsters challenged with *C. difficile* infection.³⁷⁵ However, further investigation into this approach in humans has not been successful.³⁷⁴

Recombinant monoclonal therapeutics have been shown in a randomized, double-blind, placebo-controlled study done at 30 sites in the United States and Canada to significantly reduce the recurrence rate of *C. difficile* disease (25% in the placebo group vs. 7% in the intervention group). There was no demonstrable difference in symptom severity or duration of the initial episode of diarrhea.⁴³⁶

Recommendations. Patients with refractory *C. difficile* infections (with or without a global antibody deficiency) can be treated with 300 to 500 mg/kg of IGIV every 1 to 3 weeks as adjunct therapy.^{353,469,763,762} This approach has increased antitoxin levels, controlled diarrhea, and prevented relapses during the treatment period.^{422,602} However, controlled trials have not been conducted, and this use of IGIV is not approved.^{347,353}

Studies of an oral anti-*C. difficile* bovine immunoglobulin for treatment and prevention have demonstrated anti-toxin A neutralizing activity.⁷⁵² Further development may provide a therapeutic alternative to intravenous therapy.

Gas Gangrene (*Clostridium Perfringens*)

Treatment of gas gangrene with equine antitoxin to *Clostridium perfringens* did not demonstrate efficacy and no longer is available. Food poisoning caused by *C. perfringens* is self-limited and is not treated with antitoxin.

Tetanus (*Clostridium tetani*)

Later sections discuss tetanus, tetanus antitoxin, and tetanus immunoglobulin (TIG).

Diphtheria and Diphtheria Antitoxin

Diphtheria is caused by toxigenic strains of *Corynebacterium diphtheriae* and occasionally by *Corynebacterium ulcerans*. Diphtheria has become uncommon because of widespread immunization, but a massive epidemic in the countries of the former Soviet Union occurred in the 1990s, with many fatalities.^{357,739}

The adverse consequences of diphtheria result from the toxin elaborated and absorbed from the diphtheritic membrane. The toxin acts locally by perpetuating membrane formation and is distributed through the bloodstream to the heart, nervous system, kidney, and other organs. The larger the membrane, the more toxin that is elaborated; more toxin is elaborated from membranes coating the pharynx and tonsils than from one involving the larynx and trachea.

Diphtheria toxin occurs in three forms: circulating and unbound, loosely bound to tissues, and firmly bound to tissues. Antitoxin neutralizes circulating toxin and competes with and partially neutralizes loosely bound toxin but has no effect on tissue-bound toxin. Optimal passive immunity must be initiated at an early stage of the disease by the intravenous route to intercept the toxin can before it becomes tissue bound. In the 1890s, diphtheria antitoxin was used successfully to prevent spread to newly admitted pediatric patients and nurses.²¹⁷

Antitoxin of animal origin remains the mainstay of treatment, as it was in the preantibiotic era. Diphtheria was the first illness in which antiserum was used as standard therapy. In 1901, Emil von Behring was awarded the first Nobel Prize in Medicine for this achievement. Fibiger²²⁸ proved the efficacy of diphtheria antitoxin in 1898, when he showed that 5 of 204 patients given horse antitoxin died, whereas 14 of 201 not given antiserum died. Paschlaw⁵⁴⁴ demonstrated the importance of early administration of antitoxin in 1949; the fatality rate of 197 cases treated within 48 hours was 1.96%, compared with 8.9% when

treatment was delayed until the fourth or fifth day. Other investigators have reported similar findings.^{701,702}

Tasman and associates^{701,702} emphasized the importance of intravenous administration of antitoxin because rapid achievement of high blood levels results in rapid neutralization of antitoxin and the appearance within 30 minutes of antitoxin in saliva. They showed that the mortality rate and the severity of the myocarditis and neuritis in experimental diphtheria in guinea pigs could be reduced by giving antitoxin intravenously rather than intramuscularly.

McCloskey and Smilack⁴⁶² determined the antitoxin content of standard human immunoglobulin. None of the lots tested contained diphtheria antitoxin in a sufficient titer to allow its use for antitoxin therapy. They suggested that an IGIV with higher-titer antitoxin be developed to eliminate the risk of giving horse serum intravenously. Such a product is produced and used in the Ukraine.²²²

Recommendations

Diphtheria antitoxin of equine origin is indicated for all suspected or proven cases of diphtheria.²⁶ It is available in vials containing 20,000 U from the CDC. Before administration, skin tests must be performed to determine sensitivity. If the patient has a previous history of serum reactions or the test results are positive, a schedule of desensitization as outlined earlier must be followed.

The amount of antitoxin given depends on the location and the extensiveness of the membrane, the degree of systemic toxicity, and the duration of illness. The preferred route is intravenous, although intramuscular administration has been used historically in milder cases. In all cases, diphtheria antitoxin should be given promptly rather than be delayed while awaiting bacterial confirmation of the diagnosis.²⁶

In cutaneous diphtheria, antitoxin is of uncertain value. When used, the dose is 20,000 to 40,000 U to prevent toxic sequelae. For pharyngeal or laryngeal disease, the dose is 20,000 to 40,000 U; for nasopharyngeal disease, the dose is 40,000 to 60,000 U; and for extensive disease with neck edema or disease of more than 3 days' duration, the dose is 80,000 to 120,000 U.²⁶ Although antimicrobial therapy is a valuable aid in the treatment of diphtheria, it is not a substitute for antitoxin therapy.

Routine use of antitoxin in an asymptomatic, exposed, susceptible patient is not recommended. With heavy exposure or for an extremely susceptible host, 5000 to 10,000 U of antitoxin given intramuscularly can be used in addition to antibiotics and diphtheria immunization. Proof of efficacy is lacking, however.

In 1936, Wade Hampton Frost demonstrated that diphtheria toxoid given to school children was effective in preventing disease and resultant death.²³⁶ Diphtheria antitoxin is used to prevent diphtheria and is contained in the currently used diphtheria-pertussis-tetanus (DTaP) and tetanus-diphtheria (Tdap) vaccines.

Because human IGIV has various amounts of diphtheria antitoxin, it cannot be used as a replacement for animal antitoxin.²⁶

Pertussis

Pertussis antiserum was used in the 1930s for the treatment of pertussis.¹⁰⁴ Human pertussis immunoglobulin was developed in the 1960s but was shown to have no additive benefit to antibiotics in the treatment of pertussis,^{61,488} and it is no longer available commercially.

Granström and coworkers²⁷² used an experimental human hyperimmune serum from subjects immunized with a two-component acellular vaccine to treat 33 children, and an equal number received an albumin placebo. Both groups received the same antibiotic and supportive treatment. The treated children had decreased coughing and whooping, particularly if treatment was started early in the course of disease. There was no significant difference in the duration of hospitalization. Ichimaru and colleagues³²⁸ successfully used a high-titer human IGIV preparation to treat a severely ill 1-year-old child.

Bruss and associates¹²⁰ studied a 4% high-titer human pertussis immunoglobulin in 26 children with pertussis and found that the product was safe at three dose levels (250, 750, and 1500 mg/kg). It provided good serum pertussis IgG levels with a half-life of 38 days. High titers of anti-pertussis antibodies were produced, and other studies have correlated the titers with protection against disease in animal models

after an aerosolized challenge.^{121,611} Little antibody appeared in nasal secretions. Efficacy was not evaluated in this study, but the suggestion was made that treated infants had a shorter duration of paroxysms and that the product was effective in the treatment of aerosol-induced pertussis in mice.¹²¹

A subsequent randomized, double-blind, placebo-controlled phase III trial that enrolled 25 infants was terminated because of unavailability of study product and poor recruitment. Preliminary analysis did not suggest a clinical benefit in symptoms such as cough, apnea, and oxygen desaturation in contrast to placebo.²⁹⁶

Recommendations

Because of the lack of well-designed, placebo-controlled, double-blind trials of immunomodulating agents, no recommendation exists for the role of passive immunity for pertussis.

Respiratory and Other Bacterial Infections

Respiratory tract infections caused by group A streptococci, *S. pneumoniae*, *H. influenzae* type b, and to a lesser extent, *Neisseria meningitidis*, *Chlamydia pneumoniae*, and *Mycoplasma pneumoniae* occur more frequently in patients with primary antibody deficiencies, and these infections can be reduced markedly by the regular administration of IGIV or IGIM.^{227,419,514} IGIV represents a viable adjunct treatment option for certain cases of drug-resistant bacterial infections, and there is a clear survival advantage with the use of IGIV in adult sepsis syndromes by suppressing inflammation.²²⁷ Specific animal antisera to some of these organisms were used in the early 1930s for the treatment of severe infections (e.g., meningitis), even after the introduction of sulfonamides.¹⁶ Efficacy varied but was clearly better than no treatment at all, and a combination of sulfonamides and antibody seemed to be synergistic.¹⁶

Small doses of IGIM (100 mg/kg per month) did not prevent or improve the course of respiratory infections in normal children.^{71,231} However, Nydahl-Persson and colleagues⁵¹¹ gave 24 children with repeated bacterial respiratory infection (i.e., pneumonia or otitis media) trimethoprim-sulfamethoxazole or IGIV (400 mg/kg per month). Both agents were effective in reducing the number of infections compared with a control group.

Santoshan and associates⁶⁰⁸ administered a human IGIM prepared from the sera of donors immunized with pneumococcal, meningococcal, and *H. influenzae* type b polysaccharide vaccines (i.e., bacterial polysaccharide immunoglobulin [BPIG]) to Apache Indian infants living on reservations in Arizona. Of the 703 infants studied, 222 infants in the study group received three doses of BPIG (0.5 mL/kg) at 2, 6, and 10 months of age, and the 218 infants in the control group received saline injections at the same ages. During the study period, seven cases of invasive *H. influenzae* type b disease and four cases of invasive pneumococcal disease occurred in the control group in contrast to one and two cases, respectively, in the BPIG-treated group, which was a significant difference ($P < .05$).

Otitis Media

Immunologically normal, otitis media-prone children seem to derive little preventive or therapeutic benefit from low-dose immunoglobulin given intramuscularly (100 mg/kg per month)³⁵² or intravenously (200 mg/kg per month).³⁶⁰

In patients with primary immunodeficiency, the frequency and severity of episodes of otitis media are diminished dramatically by the use of immunoglobulin in large doses. In children with secondary antibody deficiency associated with HIV infection, IGIV in large doses (400 mg/kg per month) reduced the frequency of otitis media by 60%.^{484,485} Patients with subtle immunologic abnormalities such as IgG subclass deficiencies, IgA deficiency, and polysaccharide antibody deficiencies may have recurrent episodes of otitis media that can be reduced with a large dose of IGIV (e.g., 400 mg/kg per month).^{360,389,511,638,643}

BPIG reduced the number of episodes of pneumococcal otitis media in high-risk Native American infants,⁶³⁸ but it did not decrease the total number of episodes of otitis media. Large doses of RSV-IVIG (750 mg/kg per month) reduced the frequency of non-RSV otitis

among young infants.⁶⁴⁶ This product may have high antibody titers to bacteria and other viruses.²¹³ Ishizaka and coworkers³³⁵ successfully treated seven children with recurrent pneumococcal otitis media with IGIV.

The studies previously discussed indicate that low-dose IGIM is ineffective in the prevention or treatment of otitis media, but high doses of IGIV (e.g., >400 mg/kg per month) may reduce the frequency and severity of otitis media in immunodeficient and otitis-prone normal children, probably by reducing virus- and bacteria-mediated disease.³⁰¹ Englund and Glezen²¹¹ suggested that passive immunization transplacentally from a recently immunized pregnant mother with *H. influenzae* or pneumococcal vaccine also should be considered.

IGIV should not be used routinely for otitis media-prone normal children. However, in extreme cases, it can be considered after failure of prophylactic antibiotics and pneumococcal immunization.

Sinusitis

Sinusitis is a common occurrence in immunodeficient patients and is difficult to prevent or eradicate, even with optimal treatment. Mofenson and colleagues⁴⁸⁴ found that neither IGIV (400 mg/kg per month) nor thrice-weekly sulfonamide prophylaxis prevented sinusitis from developing in children with HIV infection. Prospective data demonstrated that IGIV replacement treatment does not reduce or resolve chronic sinusitis,²²⁷ but Desrosiers and Kilty¹⁹² suggest IGIV may be an option for very refractory patients after endoscopic sinus surgery. In patients with no or subtle immune defects (e.g., IgG subclass deficiencies, polysaccharide antibody deficiencies), high-dose IGIV sometimes can decrease the frequency and severity of sinusitis.^{109,161,567,643}

Lower Respiratory Tract Infections

Although high-dose IGIV had proven benefit in preventing pneumonia in immunodeficient patients,¹²⁸ there is no evidence that it can prevent pneumonia in normal patients. Anecdotal cases of IGIV used as adjunctive therapy for refractory viral pneumonia have been reported.^{600,679}

Cystic Fibrosis

Winnie and associates⁷⁷² suggested that IGIV might improve pulmonary function in pulmonary exacerbations of cystic fibrosis. All patients received antibiotics, were older than 12 years, and had no long-term benefit from IGIV. Van Wye and coworkers⁷³¹ had similar results with the use of hyperimmune *Pseudomonas* IGIV in patients with cystic fibrosis.

A controlled trial of *Pseudomonas* hyperimmune IGIV in 116 patients with cystic fibrosis was discontinued because a 6-month interim analysis showed no reduction in acute pulmonary exacerbations.⁵⁶²

Balfour-Lynn and colleagues⁶³ suggested that high-dose IGIV had short-term benefit for improving pulmonary function and decreasing the need for steroids in selected patients with cystic fibrosis and respiratory obstruction receiving inhaled and oral steroids. In one study of 186 infants with cystic fibrosis, 92 receiving palivizumab and 94 receiving placebo over a single RSV season, the outcomes were similar for the two groups, and more research is required to recommend palivizumab prophylaxis in children with cystic fibrosis.^{583,584}

Burn Infections

Kefalides and associates³⁷² reduced the mortality rate for severely burned children by administering plasma (1 mL/kg for each 1% of surface area burned) or IGIM (1 mL/kg on days 1, 3, and 5) from 40% to 20%. They concluded that solutions containing antibodies (i.e., plasma or immunoglobulin) were more effective in reducing the complications of infections than were other colloids. However, Stone and colleagues⁶⁸¹ could not achieve any clinical benefit from IGIM therapy (0.4 mL/kg every third day until skin coverage) in 60 burned subjects compared with 40 controls.

Convalescent plasma, special immunoglobulin with high antibody titer to *Pseudomonas*, and *Pseudomonas* vaccines also have been used in burn patients in an attempt to reduce infections, but without proof of efficacy.^{180,196,349,498,637} An observational study suggested that the combined use of IGIV and polymyxin B reduced the number of septic

episodes and shortened the length of hospital stay for severely burned children.⁴⁴⁴

Firoz and colleagues²³³ summarized 5 years of experience with 82 patients with toxic epidermal necrolysis in a burn unit in San Antonio. They found no mortality benefit for the use of IGIV compared with supportive care.

Gram-Negative Infections

The most extensive use of immunoglobulin for infections in adults involved trauma, shock, and postoperative patients thought to have gram-negative infections (reviewed earlier with secondary immunodeficiency).^{74,130,188,227,260,355,795,796} In 2002, a meta-analysis involving 492 patients receiving polyclonal IGIV for sepsis and septic shock suggested a benefit, particularly among adults,¹⁴ but results of later clinical trials of the use of IGIV as an adjunctive therapy for sepsis have been mixed.¹⁵

Newborn Sepsis

Newborns and premature infants in particular are highly susceptible to bacterial sepsis and its sequelae. In addition to antibiotics, leukocytes, granulocyte colony-stimulating factor, and IGIV have been used as adjunctive therapy. Numerous studies on the prevention and treatment of newborn sepsis are available, and some suggest only slight benefit in preventing sepsis. Ohlsson and Lacy⁵²¹⁻⁵²³ reviewed the literature on the use of IGIV for suspected or proven infection in neonates and found insufficient evidence exists to support the routine administration of IGIV for neonatal sepsis. In 2011, the International Neonatal Immunotherapy Study Collaborative Group, a large collaborative study of 113 hospitals in nine countries, supported this conclusion. They evaluated the use of IGIV in neonatal sepsis and found no effect on the outcome of suspected or proven neonatal sepsis.²⁸⁴

IGIV may be considered for septic premature infants not responding well to conventional therapy, but the evidence does not support its use. It may be particularly valuable for neutropenic septic infants because it can help to mobilize leukocytes from the storage pool.

Staphylococcal Infections

Staphylococcal infections with various degrees of severity are ubiquitous. They include superficial skin infections, acute infections such as abscesses and wound infections, deep-seated indolent cellulitis, and three toxin-mediated diseases: scalded skin syndrome, toxic shock, and acute food poisoning. Antibiotics usually are effective in controlling the infections, but in some instances, the organism is antibiotic resistant or the disease is rapidly progressive. IGIV can have adjunctive benefit in some of these situations.^{373,744}

In addition to the use of IGIV, novel antistaphylococcal antibodies are being developed and tested in clinical trials. Antibody products are directed against a variety of targets on the staphylococcal organism (i.e., capsule, lipoteichoic acid, and toxins). These products are in phase I and II trials. Antibodies are being developed for prevention and treatment of staphylococcal disease.⁵¹⁹

Altastaph is a hyperimmune polyclonal immunoglobulin preparation that targets CP5 and CP8 capsular polysaccharides. It was shown to prevent *S. aureus* bacteremia in mice, but two phase II clinical trials failed to demonstrate efficacy.^{78,242,596}

Staphylococcal Toxic Shock Syndrome

Patients with staphylococcal TSS have a rapid onset of fever, shock, macular desquamating rash, and multisystem organ failure.^{21,474,628} The pathogenesis of the disorder results from infection with a strain that releases toxic shock syndrome toxin-1 (TSST-1).²¹ Approximately 20% of all staphylococcal isolates carry the gene for this toxin.⁴³⁵ TSST-1 is a potent superantigen that directly activates the 5% of T cells that have a V β 2 T-cell receptor⁴³⁵; activation results in the rapid release of multiple cytokines and a clinical picture of rapidly progressive illness. Studies have implicated methicillin-resistant *S. aureus* (MRSA) in severe TSS.³⁴¹

IGIV contains antitoxins that neutralize the staphylococcal (and streptococcal) superantigens.⁷⁰⁰ It has been used successfully in animal models of TSS²¹ and several patients.^{516,541,616} Although no controlled clinical trials have been performed for staphylococcal TSS, most authorities recommend large IGIV doses (at least 400 mg/kg) in addition to

antibiotic treatment and circulatory support.²¹ IGIV also downregulates cytokine synthesis and action and inhibits immune activation, thereby providing additional benefits.²¹

Higuchi and coauthors³¹³ reported a large family that had recurrent episodes of staphylococcal TSS associated with normal immunoglobulin levels but low serum antibody titers to staphylococcal superantigens. Two boys in the family achieved successful prophylaxis with regular IGIV infusions.

Neonatal Staphylococcal Infections

Administration of passive immunity may have value for neonatal staphylococcal infections. Infection with *S. epidermidis*, is the most common cause of sepsis in premature infants, and it is aggravated in part by the use of catheters and parenteral lipid infusions.^{58,234} Infections with *S. aureus* are also problems in neonatal ICUs. Use of passive immunity directed at reducing *S. aureus* infections has been tested.

One controlled study showed that IGIV decreased the incidence of infections but did not eliminate them.⁵⁸ This benefit has not been found in all trials of IGIV in newborns. Although the administration of IGIV increased IgG levels in newborns, the overall morbidity and death rates for nosocomially acquired sepsis were unchanged.

This variation can be explained by different amounts of staphylococcal antibodies in different IGIV brands and lots, particularly opsonic antibodies, which have been shown in animal models to be the most important correlate of clinical protection.²³⁴ Because antibody variation exists in lots of IGIV made from pools of thousands of donors, it is not surprising that Krediet and colleagues³⁹⁸ could not reliably increase the opsonic titers of premature infants by administering single-donor, fresh frozen plasma.

Because pooled IGIV has not decreased mortality rates for this high-risk population, the development of organism-specific immunoglobulin has been explored. INH-A21 (Veronate) is a plasma-derived, donor-selected, polyclonal antistaphylococcal human immunoglobulin. A phase II, multicenter, double-blind clinical trial of this antibody was conducted for 512 low-birth-weight infants (50 to 1250 g), but no clinically significant differences were seen in the incidence of *S. aureus* or coagulase-negative *Staphylococcus*.⁹¹

In a phase III trial with a larger enrollment, 1983 infants received placebo or the study drug (i.e., INH-A21). The investigators were unable to demonstrate benefit in protection against late-onset sepsis resulting from *S. aureus* or coagulase-negative *Staphylococcus*. The incidence of sepsis in the placebo group was 5% and 6% in the treatment group.¹⁸⁹

Pagibaximab is a humanized mouse chimeric monoclonal antibody directed against lipoteichoic acid, a cell wall component of gram-positive bacteria. Phase I, II, and III studies demonstrated safety and tolerability but no observed reduction in sepsis.^{546,757,758}

In the past decade, highly virulent and antibiotic-resistant strains of *S. aureus* have emerged. They are responsible for aggressive infections, including necrotizing fasciitis, and pulmonary necrosis. The virulence factors are being elucidated, and Panton-Valentine leukocidin (PVL), a product of the *pvl* gene, correlates with higher morbidity and mortality rates for patients with MRSA infections.⁹³ The precise role that PVL plays in the pathogenesis of severe *S. aureus* infections is unclear, but it may provide a target for antibody neutralization in a severe toxin-mediated disease process.¹¹³ Children with PVL-positive MRSA infections mount a robust antibody response to PVL, but the antibody does not seem to protect against future infections with the same organism.³¹¹

Neutralization of *S. aureus* PVL by IGIV in vitro has been demonstrated, and it neutralizes pore formation and the cytopathic effect of *S. aureus*.²⁴⁵ Because of this in vitro data and its use in other diseases with toxin production such as TSS, the use of IGIV in aggressive infections caused by PVL-producing *S. aureus* can be considered as adjuvant therapy along with early debridement and active antimicrobial therapy.^{300,783}

Refractory Staphylococcal Infections

Another use of immunoglobulin is for the treatment of antibiotic-resistant chronic staphylococcal infection along with intravenous antibiotics. Waisbren⁷⁴⁴ treated 16 of these patients with an antibiotic and gamma globulin combination, with recovery observed in 13 of them. Hyperimmune plasma and immunoglobulin from patients

immunized with staphylococcal toxoids are widely used in Russia with apparent success.³⁷³

Recommendations

Large doses of IGIV are indicated for the treatment of staphylococcal TSS.³⁸ The recommended regimen is a single dose of 1 to 2 g/kg or 400 mg/kg daily for 5 days. A repeated dose may be necessary because of rapid clearance of IGIV in this illness.³⁸ The value of IGIV in refractory chronic staphylococcal infections has not been proved, although anecdotal reports of efficacy exist.⁷⁴⁴

IGIV is not recommended routinely for the prevention of infection in premature newborn infants. IGIV can have adjunctive benefit in the treatment of neonates with sepsis, particularly those with neutropenia.³⁴⁴ Development of specific antistaphylococcal immunoglobulins to prevent staphylococcal infection in infants with very low birth weights continues to be an active area of investigation.⁶²⁶

Streptococcal Infections

Circulating antibody may play a role in the prevention and treatment of group A streptococcal infection.³⁶² Newborns rarely develop invasive streptococcal illness, in part because of protective transplacental antibodies.³⁶² Equine antitoxin was used with some success in the treatment of erysipelas and scarlet fever in the 1920s and 1930s.^{438,690}

Invasive Group A Streptococcal Infections

Invasive group A streptococcal infections, including septicemia, necrotizing fasciitis or myositis, and TSS, are increasing in severity and frequency.²⁷ Streptococcal pyrogenic exotoxins, including types A, B, and C, and mitogenic factor elaborated by certain strains of streptococci may be responsible for these serious complications of infection. Streptococcal pyrogenic exotoxins are potent superantigens that activate certain T lymphocytes directly and lead to the massive production of multiple cytokines, with resultant shock, fever, and organ failure. IGIV contains neutralizing antibodies that respond to these antigens,^{508,509} but the titers vary across batches.⁶¹⁸

Patients with invasive soft tissue infections with group A *Streptococcus* may benefit from high-dose IGIV.^{182,258,508} In contrast to these reports, Mehta and colleagues⁴⁷² could not document a benefit for IGIV in patients admitted to the ICU with invasive group A infections from any cause.

Streptococcal Toxic Shock Syndrome

Many case reports have attested to the value of IGIV in streptococcal TSS since the report by Barry and coauthors in 1992.^{17,72,185,417,431,553} Kaul and colleagues³⁶⁸ reported a study of 21 consecutive patients at several Canadian medical centers in 1994 and 1995 who were treated with IGIV and compared them with 32 similar patients not given IGIV at the same centers for the 3 preceding years. Both groups received appropriate antibiotics and were similar with regard to demographics, severity score, and timing of intervention. The median IGIV dose was 2 g/kg. The survival rate for the IGIV-treated group was significantly greater at 7 and 30 days (90% and 67%, respectively) than that for the untreated controls (50% and 34%, respectively; $P = .02$), and the days of hospitalization were insignificantly shortened (29 vs. 39). Serum from the IGIV-treated patients caused a marked inhibition of lymphocyte mitogenic activity to their own bacterial isolates after a single IGIV dose. This study excluded children from the analysis because of ethical considerations and the overall lower mortality rate for the younger age groups.

In a large, multicenter, retrospective trial of children with streptococcal TSS,⁶²⁵ IGIV was administered to 84 of 192 children with streptococcal TSS, and the overall mortality rate and overall hospital and drug costs were evaluated. The investigators found no added benefit of IGIV infusion and reported the increased costs for IGIV administration. However, in a study by Linner and colleagues that was reported in 2014, both IGIV and clindamycin therapy contributed to significantly improved survival of patients with streptococcal TSS.⁴³¹

PANDAS Syndrome and Sydenham Chorea

Murphy and colleagues⁴⁹³ and Swedo and coauthors⁶⁸⁹ reported a syndrome of tics or obsessive-compulsive behavior, or both, occurring

in prepubertal children soon after the onset of a streptococcal infection. They called the syndrome pediatric autoimmune neuropsychiatric disorders associated with streptococcal disease (PANDAS). They suggested a benefit for treatment of PANDAS with IGIV.⁵⁵⁴ The National Institute of Mental Health is conducting a trial examining the benefits of IGIV for patients with PANDAS (<http://clinicaltrials.gov/ct2/show/NCT01281969>).

Sydenham chorea is a movement disorder that follows streptococcal infection. Successful treatment of Sydenham chorea with IGIV has been anecdotally reported.^{729,746}

Recommendations

The use of IGIV can be considered as adjunctive therapy for TSS or necrotizing fasciitis in severely ill patients. Various regimens of IGIV, including 150 to 400 mg/kg per day for 5 days or a single dose of 1 to 2 g/kg, have been used, but the optimal regimen is unknown.²⁷ Repeated administration of IGIV may be necessary after a few days because of rapid IGIV catabolism.

IGIV may be beneficial for severe streptococcal soft tissue infections such as necrotizing fasciitis. IGIV has no proven benefit in PANDAS syndrome,⁵²⁸ but studies are ongoing.

Tetanus, Tetanus Antitoxin, and Tetanus Immunoglobulin

Antitoxin for the treatment of tetanus was introduced into medicine by Behring and Kitasato in 1890; large doses (50 to 100 mL) of serum from horses immunized with tetanus toxin were used. The dose was increased gradually to 300 to 500 mL, which is equivalent to 300 to 500 U of antitoxin. As the means to increase the production and concentration of antitoxin developed and a high mortality rate persisted, the dosage of antitoxin was increased until doses as high as 200,000 U, repeated at weekly intervals, were recommended.⁵⁴⁹ Despite such heroic therapy, no solid proof of efficacy was obtained.

In 1960, Brown and colleagues¹¹⁵ using sequential analysis, found that the mortality rate was 49% for 41 patients with tetanus who received 200,000 U of antitoxin, a statistically significant difference that established therapeutic efficacy. Extensive controlled studies established that mortality rates did not improve when larger doses (100,000–500,000 U) were used.^{437,722–724}

Similarly, Patel and associates⁵⁴⁷ could find no difference in the mortality rates of patients with tetanus treated with antitoxin doses of 5000 to 60,000 U. Adequate blood levels of antitoxin were observed in all cases, even in fatal cases, with a dose of 10,000 U. In mild cases, no antitoxin was necessary. They and others have reported considerable differences in mortality rates, ranging from 0% to 98%; the rate depends primarily on the severity of illness rather than on the dose of antitoxin.

Athavale and colleagues⁵⁴ established that antitoxin had benefit in tetanus neonatorum and in tetanus in children up to 12 years of age. Antitoxin affected the mortality rate in mild and moderate cases but not in severe ones. A dose of 10,000 U was as effective as one of 30,000 U.

The mechanism of action of antitoxin is to neutralize the toxin before it is transported to the nervous system through the circulation. Antitoxin also can neutralize toxin locally and prevent its systemic absorption. Antitoxin can be given locally at the site of production of toxin (e.g., site of a wound), intravenously in severe cases, or intramuscularly in less severe cases.

In 1962, an estimated 750,000 annual doses of equine tetanus antitoxin were needed in the United Kingdom, which is equivalent to more than a million doses in the United States.⁵⁹⁴ Serum sickness occurs in 6% to 14% and fatal anaphylaxis in 1 of 100,000 injections of equine-derived antitoxin. Hyperimmune human tetanus immunoglobulin (TIG), first available in the early 1960s, gradually has replaced equine tetanus antitoxin.

Rubbo and Suri⁵⁹³ and Rubinstein⁵⁹⁴ showed that TIG given intramuscularly (5–10 U/kg) provides adequate circulating antitoxin levels. It is maintained in the circulation for considerably longer than is equine tetanus antitoxin.

The efficacy of TIG is equivalent to that of equine tetanus antitoxin. McCracken and associates⁴⁶⁴ compared the results of 550 U of TIG with 10,000 U of tetanus antitoxin in the treatment of tetanus neonatorum. Among the 65 infants in each treatment group, no difference was observed

in severity, length of hospitalization, need for sedation or gavage feeding, or mortality rate. Blake and colleagues⁸⁸ analyzed 545 tetanus cases reported to the CDC from 1965 to 1971 and found no difference in the outcome of patients treated with equine tetanus antitoxin or TIG.

The first use of intrathecal antitoxin was recorded in 1898 by Charles Church and Rambord from the Pasteur Institute and by Cushing in 1899.⁵⁴⁹ In 1902, a French surgeon reviewed 27 cases of tetanus treated with intrathecal antitoxin and concluded that there was no additional benefit.⁷⁶⁹

Gupta and associates²⁹¹ gave TIG intrathecally to alternate patients with early tetanus. Among 49 patients given intrathecal TIG (250 U), three deteriorated, and one died; among 48 patients given intramuscular TIG (1000 U), 15 deteriorated, and 10 died. No side effects occurred. Herrero and coworkers³¹² could not prove a benefit for administering intrathecal antitoxin for tetanus neonatorum. Although an early meta-analysis of intrathecal therapy cast doubt on its efficacy,⁵ studies from India²⁴⁷ and Brazil⁴⁷⁸ and a larger meta-analysis³⁵⁶ suggested a beneficial effect for intrathecal antibody.

TIG can be given along with tetanus toxoid for passive-active immunization. A dose of 250 U of TIG given intramuscularly at a site different from that of the toxoid does not interfere with the active antibody response.⁴⁶³

Lee and Lederman⁴²⁰ measured the tetanus antitoxin titers in 29 lots of IGIV and found considerable variation, although all lots had titers greater than 4 U/mL (mean, 21 U/mL). All lots would provide sufficient anti-tetanus toxin antibody if used at doses of 100 mg/kg as an alternative to TIG or tetanus antitoxin.

Recommendations

Prophylaxis. If a nonimmunized person sustains a serious injury or a bite, 250 to 500 U of TIG should be given intramuscularly as soon as possible.³⁸ A larger dose is used in the event of an extensive wound or delay in treatment. TIG is available for intramuscular administration in individual vials containing 250 U. Alum-precipitated toxoid to initiate active immunity is given at a different site with a separate syringe.

Human IGIV also can be used if TIG is not available and should be administered at a dose of 200 to 400 mg/kg.³⁸ The use of IGIV is not FDA approved and the anti-tetanus antibody levels in IGIV are not routinely assessed.

If TIG or IGIV is unavailable, tetanus antitoxin (equine) can be administered after screening and testing for serum sensitivity have been performed.³⁸ Equine antitoxin for human use is available in several countries, but not in the United States, where TIG is available.

Treatment. In addition to administration of antibiotics and management of the wound, TIG should be given, but the optimal dose has not been established. At least 500 U is recommended, but doses as high as 3000 to 6000 U have been used. Some of the TIG is infiltrated near the wound, and the remainder is administered intramuscularly.³⁸ If the wound is extensive, TIG can be diluted with saline to infiltrate the entire area. TIG also is indicated for the treatment of tetanus neonatorum. Recent meta-analyses suggest that intrathecal use is beneficial for adults and infants.³⁵⁶ A study of infants with neonatal tetanus showed mild improvement in outcome in infants who received intrathecal TIG.¹¹

Equine tetanus antitoxin has been used when TIG is unavailable, but this product is not available in the United States. It should be given in a single dose of 100,000 U, with 50,000 U given intramuscularly and 50,000 given intravenously after appropriate testing for sensitivity. On recovery, the patient should undergo primary immunization.

McCracken and associates⁴⁶⁴ found that 500 U of TIG given intramuscularly and 10,000 U of equine antitoxin were equally efficacious for tetanus neonatorum. Intrathecal TIG has been recommended in certain clinical situations,^{291,356,469} but it is not always beneficial.^{77,312} TIG is not licensed for intrathecal use.

PASSIVE IMMUNITY IN VIRAL INFECTIONS

Enteroviruses

Poliovirus

Before the development of poliomyelitis vaccines in the mid-1950s, IGIM was used extensively for the prevention of poliomyelitis. Bodian^{94,95}

showed that Red Cross IGIM had neutralizing antibody to all three strains of poliovirus in approximately equal titers and that rhesus monkeys given intramuscular poliovirus could be protected against disease by the subcutaneous administration of IGIM.

Bloxson,⁹² in an uncontrolled study performed during a 1948 Texas epidemic, gave 841 contacts an average dose of 2 mL of IGIM and observed only four cases at 1, 2, 3, and 42 days after administration of the IGIM injection. His interpretation was that IGIM had been given too late to prevent the first three cases and that protection had worn off in the fourth case.

A committee on immunization of the National Foundation for Infantile Paralysis recommended in March 1951 that a controlled study be conducted on the efficacy of IGIM for the prevention of poliomyelitis during epidemics. Hammon and associates²⁹⁹ subsequently undertook a massive field study in communities in three states during poliomyelitis epidemics.

Fifty-five thousand children between the ages of 1 and 11 years received IGIM (average dose, 0.14 mL/lb) or gelatin in a double-blind fashion. During the first week after injection was administered, 12 cases occurred among the IGIM recipients and 16 cases among the gelatin recipients. In the two groups, 3 and 23 cases occurred in the second week and 6 and 38 cases occurred in the third to fifth weeks, respectively. When protection was incomplete, decreased severity was observed. Protection waned by 6 weeks and disappeared by 8 weeks. These clinical results were confirmed by isolation of the virus or a rise in antibody titer in affected patients.

IGIM was an inefficient method of poliomyelitis prophylaxis in that it prevented only one case for every 500 to 2000 injections and only for a brief time. Its chief value was for close family contacts of affected children and for aborting severe local epidemics. IGIV failed to improve outcomes of patients with postpolio syndrome.^{84,395}

Recommendations. The use of IGIM rarely is indicated for the prevention of poliomyelitis. An exposed unimmunized subject can be given 0.31 mg/kg of IGIM. An unimmunized patient who is traveling to an endemic or epidemic area and who cannot have vaccine can be given this dose of IGIM for temporary protection.

An immunodeficient patient inadvertently exposed to live attenuated polio vaccine who is excreting poliovirus in stool may be a candidate for receiving IGIV and oral immunoglobulin in an effort to rid the gastrointestinal tract of the virus.

Other Enteroviruses

Enteroviruses, particularly echoviruses and coxsackieviruses, can cause severe disease in neonates^{334,429} and in immunodeficient patients, particularly those with X-linked agammaglobulinemia or common variable immunodeficiency.⁵⁷⁷ IGIM and IGIV have been used in both groups for the prevention and treatment of these infections.⁵⁷⁷

Meningoencephalitis. Chronic enteroviral meningoencephalitis with severe neurologic findings may develop in agammaglobulinemic patients; however, the incidence has decreased since routine treatment with IGIV has been instituted for these patients. IGIV does not prevent all cases, likely as a result of different titers of antibodies to different enteroviral serotypes. McKinney and coworkers⁴⁶⁷ summarized the results of treatment of 42 patients with chronic enterovirus meningoencephalitis: 10 received IGIM or plasma (one survived), 10 received IGIV (seven survived), and 12 received both intraventricular IGIV and systemic IGIV (10 survived).

Misbah and colleagues⁴⁸⁰ reviewed 15 patients with chronic enteroviral meningoencephalitis not included in the McKinney report, some of whom had been described by others.^{202,394} Of the five patients treated with IGIV, three survived, and of 10 treated with IGIV and intraventricular or intrathecal IGIV, five survived. Mellouli and colleagues⁴⁷⁵ successfully treated an agammaglobulinemic boy who developed echovirus meningoencephalitis while receiving IGIV with intraventricular immunoglobulin through an Ommaya reservoir in addition to aggressive intravenous therapy.

Quartier and associates⁵⁶⁵ reported complete clinical and virologic remission in two patients with X-linked agammaglobulinemia, as determined by culture and polymerase chain reaction (PCR) assay. The first patient was treated with IGIV and a brief course of pleconaril. The

second patient was treated with IGIV and pleconaril, but intraventricular immunoglobulin was added when CSF pleocytosis persisted after 11 months of therapy. Complete clinical and virologic remission persisted at the 20-month follow-up. This study indicated that CSF PCR assay can be used in addition to viral culture as a guide to successful therapy.

Neonatal enteroviral infection. Severe and sometimes fatal disseminated enterovirus infection can develop in neonates.⁵⁶⁶ Case reports have suggested a benefit with the use of IGIV.^{334,348,726} Kimura and coworkers³⁸⁴ treated coxsackievirus B3 infection in four term infants with IGIV. The three who were treated early survived, but the infant treated 6 days after the onset of infection died. Abzug and associates⁶ treated nine infants with echovirus and coxsackievirus B infection with IGIV but without apparent benefit; however, three of five infants who received high-titer IGIV had a shortened period of viremia. Rentz and colleagues⁵⁷⁸ suggested that the maternal plasma might be used in lieu of IGIV as a source of high-titer antibody for newborns with a severe enteroviral infection. Yen and colleagues evaluated the benefit of IGIV therapy for severe neonatal enteroviral infections and found that serum aspartate aminotransferase (AST) levels correlated with disease severity and that early IGIV therapy could improve survival.⁷⁸⁵

Nagington and colleagues⁴⁹⁴ used IGIM successfully in an echovirus 11 outbreak in a special care nursery, but Kinney and coworkers³⁸⁵ could not demonstrate a benefit for using IGIM in a similar nursery with the same virus. Pasic and associates⁵⁴⁵ administered IGIV at 400 mg/kg prophylactically during a nursery echovirus 6 outbreak and thought that the severity of illness was decreased, although viral transmission continued.

Recommendations. IGIV may be used for critically ill neonates with disseminated enterovirus infection, although its benefit has not been proved. In an outbreak situation with a known serotype and the availability of IGIV with significant titer to this serotype, IGIV should be considered.⁷⁰⁴ Multiple doses of 500 mg/kg and single doses of 750 to 1000 mg/kg have been used.^{6,348,384,726}

For chronic enteroviral meningoencephalitis, McKinney and colleagues⁴⁶⁷ recommend that sufficient IGIV be administered to maintain an IgG serum trough level of 900 to 1000 mg/dL. Higher doses may be needed if the IGIV titer for the infecting virus is low. Quartier and coworkers⁵⁶⁵ used 500 mg/kg of IGIV every 24 to 48 hours for 2 weeks, followed by 500 mg/kg two to three times per week for 6 weeks and then gradual reductions, but with maintenance of the trough IgG level at greater than 800 mg/dL.

Administration of IGIV by intraventricular catheter should be considered for patients who do not improve despite receiving aggressive therapy with IGIV. IGIV for intraventricular administration should have a neutral pH, be given slowly, and be at room temperature.⁴⁶⁷ Dwyer and Erlendsson²⁰² used 6% IGIV intraventricularly, starting at doses of 120 mg/day and increasing to 600 mg/day during the first week of treatment, followed by doses of 300 mg/day for 1 to 4 weeks. Quartier and colleagues⁵⁶⁵ administered 300 mg of IGIV daily for 15 days and then 300 mg three times per week to a patient whose intravenous IGIV therapy had failed. The duration and frequency of intraventricular immunoglobulin and IGIV must be individualized and determined by clinical and virologic response and normalization of CSF and ventricular fluid. IGIV with a high titer to the infecting serotype should be used for systemic and intraventricular therapy.

Hepatitis A

The widest use for human IGIM has been for the prevention of hepatitis A, but this indication has been decreased by the widespread use of hepatitis A vaccine.²⁸ The efficacy of IGIM was demonstrated in 1945 by Stokes and Neefe⁶⁸⁰ in aborting an epidemic in a children's summer camp, by Havens and Paul³⁰⁴ in controlling an institutional epidemic, and by Gellis and associates²⁴⁸ in preventing hepatitis A in the Mediterranean theater of operations at the close of World War II. The administration of combined IGIM and hepatitis A vaccine and scrupulous cleanliness can be used to interrupt the intestinal-oral circuit of transmission to abort an incipient epidemic.

IGIM is efficacious in preventing hepatitis A if it is given within 2 weeks of the last exposure.^{9,28} Protection typically persists for 6 to 8 weeks. Stokes and associates⁵⁷⁷ found that a single dose of IGIM (0.02 mL/

kg) provided a degree of protection for up to 9 months in individuals residing at an institution in which hepatitis A was endemic.

The effectiveness of IGIM in hepatitis A varies from 80% to 95%, depending on how soon it is administered after exposure and the severity of the exposure.⁷⁵⁰ IGIM suppresses clinical manifestations of the disease, but anicteric hepatitis is not prevented, and the ratio of anicteric to icteric hepatitis may be as high as 12:1.⁴⁰⁴ The period of protection exceeds the expected duration of the IGIM, supporting the concept of passive-active immunity. The hypothesis is that as a result of continuous exposure, a mild illness ensues, which confers long-lasting immunity.^{404,676,749}

In initial studies, Stokes and Neefe⁶⁷⁹ used an IGIM dose of 0.15 mL/lb, whereas others used doses of 0.06 to 0.12 mL/lb.^{250,304} In 1951, Stokes and associates⁶⁷⁷ showed that doses as low as 0.01 mL/lb were effective in limiting spread but did not completely prevent hepatitis. Hsia and colleagues³²² in 1954 also found that a dose of 0.01 mL/lb was effective in preventing hepatitis among family contacts. However, in 1958, Ward and associates⁷⁵¹ were able to reduce the case incidence of hepatitis among institutionalized patients from 19.5 to 7.4 cases per 1000 patients with 0.01 mL/lb and 1.7 cases per 1000 patients with 0.06 mL/lb. The larger dose may be particularly important for adults because they are subject to more severe disease.

The use of serologic tests for hepatitis A provides a way to determine the immunity of a subject, the presence of inapparent infection, the titer of hepatitis A virus (HAV) in lots of IGIM, and the validity of the passive-active immunity concept.^{577,680} In other earlier studies, Krugman⁴⁰⁰ showed that an IGIM preparation with a titer of 1:3200 was effective in neutralizing the infectivity of MS-1 serum, a substance that contains HAV. Farcet and colleagues evaluated the HAV antibody titer in plasma pools from March 2003 through September 2008 and determined the HAV titers adequate for HAV protection for those receiving antibody replacement for primary immune deficiency.²¹⁹

Most current lots of IGIM have anti-HAV antibodies when they are assayed by a competitive-inhibition radioimmunoassay. Titers greater than 1:100 are protective.⁶⁵¹

Recommendations

Household and sexual contacts. All previously unimmunized people with close contact with a person with HAV should be given a single IGIM dose of 0.02 mL/kg or single-antigen hepatitis A vaccine as soon as possible after being exposed.^{9,28,735} For healthy people between the ages of 12 months and 40 years, single-antigen hepatitis A vaccine at the age-appropriate dose is preferred. For those older than 40 years, those younger than 12 months, immunocompromised individuals, people who have had chronic liver disease, and those for whom vaccine is contraindicated, IGIM is preferred.⁵⁰⁴ Serologic testing for hepatitis A is unnecessary and may delay the administration of IGIM. The use of IGIM longer than 2 weeks after exposure has occurred but is not indicated.^{28,232}

School exposure. IGIM usually is not necessary for children and their teachers exposed to a single case of hepatitis A in the classroom of a day school. However, if several children are infected or if transmission in the school is documented, IGIM (0.02 mL/kg) or vaccination is indicated for unimmunized students and teachers who have close contact with the index case. IGIM prophylaxis is recommended for children and staff exposed at a boarding school or in a school for developmentally disabled children, where opportunities for transmission by the fecal-oral route are increased.

Institutional outbreaks. Hepatitis A outbreaks in institutions such as boarding schools, childcare centers, custodial care centers, and prisons require aggressive action; however, the frequency of these outbreaks have decreased with increasing vaccination rates. Vaccine or IGIM should be administered to all previously unimmunized staff members and attendees if one or more cases of hepatitis A are recognized among children or staff or two or more cases among households with attendees at the centers. Vaccine or IGIM should be given to all household members with those in diapers at the centers if two or more families are affected.^{9,28} If an outbreak of hepatitis A is traced to a food handler, IGIM or vaccine should be given to close contacts and other restaurant employees.¹³⁶

Hospital and clinic exposure. When an outbreak occurs, vaccine or IGIM is recommended for people in close contact with the infected patient.⁹

Common source exposure. Common source exposure cases usually are identified too long after the exposure occurs for IGIM to be effective. If a person has been exposed within the previous 2 weeks, IGIM or vaccine can be given (0.02 mL/kg).⁹

Community outbreaks. Unless a source of the infection is identified, mass use of IGIM is ineffective and not recommended because it will not interfere with transmission.⁵³ Immunization is recommended.

Foreign travel. Individuals going to developing countries should receive vaccine 1 month before departure. Travelers who are administered vaccine can be assumed to be protected within 4 weeks after receiving the first vaccine dose.^{148,232} If the departure date is less than 2 weeks away, 0.02 mL/kg of IGIM and vaccine can be used.²⁸ IGIM provides immediate protection and does not interfere with efficacy of the vaccine. If exposure to hepatitis A will continue beyond 3 months, the IGIM dose should be 0.06 mL/kg and repeated every 5 months if exposure to hepatitis A continues and the patient cannot be immunized.⁹

Primate exposure. Certain subhuman primates such as chimpanzees can carry HAV. Animal handlers should observe scrupulous hygiene and be given hepatitis A vaccine. If bitten and unimmunized, they should receive 0.02 mL/kg of IGIM and vaccine.¹⁴⁸

Needle exposure. IGIM is indicated for susceptible people accidentally inoculated with blood or serum from a patient with hepatitis A. The recommended dose is 0.02 mL/kg; pregnancy is not a contraindication to the administration of IGIM.

Newborn infants of infected mothers. Perinatal transmission of HAV is rare. If the mother becomes symptomatic with acute hepatitis A between 2 weeks before and 1 week after delivery, the infant can be given 0.02 mL/kg of IGIM. Efficacy has not been established.¹⁴⁸

Hepatitis B and Hepatitis B Immunoglobulin

Hepatitis B virus causes a wide spectrum of illness, ranging from asymptomatic seroconversion to fulminant hepatitis. Although most healthy patients recover completely, the carrier state occurs commonly in exposed immunocompromised patients, such as newborns, patients taking immunosuppressive medications, and patients with primary or secondary immunodeficiencies.

Transmission occurs after exposure to blood or other body fluids, through inoculation or sexual contact, and by close personal contact such as may occur in childcare centers. The main route of transmission used to be by blood transfusion, but with donor testing, this route is no longer common in developed countries. An important route of perinatal transmission is from the mother to the newborn infant, who is likely to remain chronically infected for a lifetime. This route usually can be prevented by active and passive immunization.

Immune Globulin Use in Hepatitis B

The initial study of IGIM in hepatitis B was conducted in 1945 by Grossman and associates,²⁸³ who treated alternate battle casualties given whole blood or plasma with two 10-mL injections of IGIM 1 month apart. The incidence of icteric hepatitis was 1.3% among 384 IGIM-treated patients and 9.9% among 384 control patients. The highly significant difference suggested a beneficial effect of IGIM.

In 1947, Duncan and associates²⁰⁰ reported the results from a similar study, although they gave only one 10-mL injection. Hepatitis occurred in 1.2% of 2406 patients in the IGIM-treated group and in 0.9% of patients in the control group, which was an insignificant difference. However, the mean incubation period was significantly prolonged for the IGIM-treated group (to 103 days) compared with the control group (87 days).

Holland and associates³¹⁷ could not alter the incidence or severity of posttransfusion hepatitis for 84 open-heart surgery patients by giving two 10-mL doses of IGIM 1 month apart compared with 83 non-IGIM-treated controls. These findings were confirmed in a large cooperative study of 5189 transfused cardiovascular patients given 10 mL of IGIM during the first, fourth, and seventh postoperative weeks.²⁶⁸ Redeker and associates⁵⁷⁴ could not demonstrate that IGIM protected spouses of individuals with type B hepatitis. Similarly, Kuhns and colleagues⁴⁰⁷

could not reduce the incidence of posttransfusion hepatitis B with 20 mL of IGIM. Both latter studies used IGIM with low titers of antibody to hepatitis B surface antigen (anti-HBs).

Several factors probably are responsible for the variation in effectiveness of IGIM in hepatitis B. One is the degree of exposure to hepatitis B virus, which can be massive (e.g., blood transfusion) or minimal (e.g., household contact). A second factor is the different levels of antibody to hepatitis B surface antigen (anti-HBs) in different lots of IGIM. Because IGIM does not always contain high titers of anti-HBs, it is not recommended for hepatitis B prophylaxis. Standard immunoglobulin is not effective for postexposure prophylaxis against HBV infection because the concentration of anti-HBs is too low.²⁹

Hepatitis B Immunoglobulin

Soon after hepatitis B surface antigen (HBsAg) and its antibody (anti-HBs) were identified, researchers could measure and select lots (or donors) with titers of anti-HBs of at least 1:100,000 by radioimmunoassay. This product, hepatitis B immunoglobulin (HBIG), has been licensed since 1978 for the prevention of hepatitis B.^{28,140,142}

In 1971, Krugman and associates^{401,404,405} evaluated high-titer HBIG in institutionalized children injected with the infective serum MS-2. Hepatitis developed in all 11 children exposed to MS-2 serum, and five remained HBsAg carriers after 320 days. Among five children given MS-2 serum and standard immunoglobulin, hepatitis developed in three, but none became a carrier. Of 10 children exposed to MS-2 serum and HBIG, six were completely protected, one had a transient infection, and three developed classic hepatitis. They concluded that HBIG was 70% effective under these circumstances. Their later studies confirmed that HBIG could reduce the incidence, severity, and carrier rate of HBsAg significantly after prenatal exposure to hepatitis B virus.⁴⁰²

Szmunes and associates⁶⁹¹ tested the efficacy of HBIG versus IGIM by giving standard IGIM or HBIG to institutionalized children at admission and at 4-month intervals for 1.5 to 2 years and compared the incidence of hepatitis with that among untreated patients. Both globulin-treated groups had a lower attack rate (11% [treated] vs. 25% [untreated]) and a lower incidence of persistent hepatitis B antigen (0% [treated] vs. 13.5% [untreated]). IGIM and HBIG were effective in preventing or modifying nonparenterally transmitted hepatitis B in an endemic setting. Anti-HBs developed in 55% of the patients treated with standard IGIM, whereas antibody developed in only 23% of the patients treated with HBIG, suggesting that passive-active immunity occurred more frequently in the group that received standard IGIM than in the group that received HBIG.

Seeff and associates⁶²⁰ gave HBIG or standard IGIM to 302 individuals definitively exposed orally or parenterally to material that was infectious for hepatitis B. The incidence of clinical and subclinical hepatitis during the first 6 months was 0.7% for the HBIG-treated group and 6.1% for the IGIM-treated group. At 6 months, 32% of the IGIM recipients and 6% of the HBIG recipients had antibody, a finding indicative of minimal passive-active immunity in the HBIG-treated group.

Grady²⁶⁹ reported similar results with HBIG after accidental exposure. The incidence of hepatitis at 6 months was 7% (of 251 patients) with standard IGIM, 5% (of 208 patients) with intermediate-titer HBIG, and 2% (of 253 patients) with high-titer HBIG. This protection waned after 6 months, and differences in the groups became less apparent after 9 months, possibly because of reexposure, delayed onset of infection, or failure of passive-active immunity.

Prevention of Vertical Transmission

Beasley and associates^{75,76} studied the efficacy of HBIG in preventing perinatal transmission of the hepatitis B virus carrier state from a mother to her newborn infant. HBIG or placebo was given at birth to the infants of hepatitis B early antigen (HBeAg)-positive, HBsAg-positive carrier mothers, and the infants were monitored for at least 15 months. Of 61 placebo recipients, 92% became carriers; of 67 infants who received 1 mL of HBIG at birth, 54% became carriers; and of 57 infants who received 0.5 mL of HBIG at birth and at 3 and 6 months, 26% became carriers. Passive-active immunization, indicated by the presence of anti-HBs, occurred in 27% of the single-dose group and in 61% in the three-dose group.

On the basis of these and other studies^{346,577} suggesting that multiple HBIG doses were more effective in interrupting vertical transmission of the HBsAg carrier state than a single HBIG dose, advisory committees in the early 1980s recommended that all infants of HBsAg-positive mothers be given HBIG (0.5 mL) immediately after birth and again at 3 and 6 months.^{140,142} However, many of these infants became infected sometime after their last HBIG dose (i.e., in the second or third year of life), indicating a need for more durable active immunity. Shi and colleagues⁶³³ systematically reviewed the effect of HBIG given in pregnancy to interrupt mother-to-child transmission of hepatitis B. They evaluated 37 randomized, controlled trials between January 1990 and December 2008 and concluded that there may be some benefit in HBIG use in pregnancy to prevent intrauterine transmission.

Wong and associates⁷⁷⁸ studied the efficacy of hepatitis B vaccine given in conjunction with HBIG in the prevention of vertical transmission of the carrier state from mother to infant. They gave hepatitis B vaccine (36 infants), hepatitis B vaccine plus one dose of HBIG (35 infants), hepatitis B vaccine plus seven monthly HBIG doses (35 infants), or placebo (35 infants) to infants of HBsAg-positive mothers. In all vaccine groups, development of a persistent carrier state was reduced significantly compared with the placebo group (21% with hepatitis B vaccine alone, 2.9% with hepatitis B vaccine plus one dose of HBIG, and 6.8% with hepatitis B vaccine plus seven doses of HBIG vs. 73.2% for placebo groups). Anti-HBs developed in all infants of the treatment groups, indicating that HBIG did not interfere with active immunization.

This and other studies⁶⁹³ indicate that HBIG given at the same time as hepatitis B vaccine provides optimal passive-active immunity for long-lasting prevention of the carrier state, and this dose of 0.5 mL is the current recommendation. Studies of adults confirm that HBIG given before or simultaneously with the first dose of hepatitis B vaccine does not interfere with the antibody response to hepatitis B vaccine.⁷⁸⁹ This approach can protect 85% to 95% of infants from perinatally acquired HBV infection.¹⁵¹

HBIG is not of value in the treatment of acute⁷ or chronic⁵⁷⁶ hepatitis B infection.

Hepatitis B Immunoglobulin in Liver Transplantation

Liver transplantation in a patient infected with hepatitis B is associated with a high rate of its recurrence in the new liver and subsequent death (50% in 2 years). Intravenous HBIG has proven efficacy and a dose-dependent response in the prevention of HBV recurrence after liver transplantation.¹⁷⁰ It has been the mainstay of posttransplantation prophylaxis for recurrent HBV since the early 1990s.¹²³ The HBIG doses needed to prevent reinfection are very high, and HBIG primarily is given intravenously.⁷⁰⁶

HBIG given intravenously or by the usual intramuscular route can reduce the rate of recurrence of hepatitis B.⁶⁰³ In a retrospective analysis of 359 transplantations, the rate of hepatitis B recurrence was 74% ± 6% among 67 patients given no HBIG, 74% ± 5% among 83 patients given HBIG for 2 months, and 36% ± 4% among the 209 patients given HBIG for 6 months or longer.

Grazi and coworkers²⁷⁴ reduced significantly the recurrence rate in HBsAg-positive, hepatitis B virus DNA-negative cirrhotic individuals undergoing liver transplantation with the use of HBIG for 1 year after transplantation. Recurrence was seen in 8 (80%) of 10 controls and four (16%) of 25 HBIG-treated patients. Other reports are available.^{703,705}

In addition to HBIG therapy, pretransplantation and posttransplantation antiviral drugs such as lamivudine or entecavir are used. When administered in the immediate pretransplantation period to patients with a high viral burden, these drugs enhance the effectiveness of HBIG because less virus must be neutralized.^{13,323,366,585,703} Long-term maintenance of antivirals with discontinuation of HBIG after several months may be feasible.^{164,719,777}

Preliminary studies of monoclonal antibodies to hepatitis B antigens are being conducted.^{155,264,794}

Recommendations.

Prophylaxis. HBIG is recommended after a person's parenteral or mucous membrane (e.g., oral, sexual, ophthalmic) has contact with blood or body fluids from individuals with hepatitis B or with

TABLE 246.4 Postexposure Recommendations for Hepatitis B Immunoglobulin and Hepatitis B Vaccine

Type of Exposure to Hepatitis B	HEPATITIS B IMMUNOGLOBULIN		HEPATITIS B VACCINE	
	Dose	Recommended Timing	Dose	Recommended Timing
Perinatal				
Infant of HBsAg-positive mother	0.5 mL IM	Within 12 h of birth	0.5 mL	First dose within 12 h, repeat 2 times
Infant of mother whose HBsAg status is unknown	0.5 mL IM	Within 7 days of birth if mother is found to be HBsAg positive	0.5 mL	First dose within 12 h, repeat 2 times
Premature infant (<2000 g) whose mother's HBsAg status is unknown	0.5 mL IM	Within 12 h of birth (unless maternal HBsAg test result is negative by this time)	0.5 mL	First dose within 12 h, repeat 3 times
Mucous Membrane or Percutaneous With Known Nonoccupational Exposure				
Nonvaccinated	0.06 mL/kg IM	Immediately	0.5 mL ^a	First dose immediately, repeat 2 times
Previously vaccinated, known responder	None	None	None	—
Previously vaccinated, unknown response	0.06 mL/kg IM	Test patient for anti-HBs; omit HBIG ^b if anti-HBs is >10 mIU/mL	0.5	Give booster ^b
Previously vaccinated, known nonresponder	0.06 mL/kg IM	Immediately, may repeat in 1 mo if <10 mIU/mL ^c	0.5 mL ^a	Give booster immediately, repeat 2 times if necessary
Sexual, Known Exposure				
Nonvaccinated	0.06 mL/kg IM	Immediately, but no later than 14 days	0.5 mL ^a	First dose immediately, repeat 2 times
Vaccinated ^b	None	None	0.5 mL	Give booster if unknown response

^aDose is for individuals younger than 20 years. The adult vaccine dose is 1 mL. The dose for immunosuppressed patients and patients undergoing dialysis varies with the vaccine used. Vaccine doses given in the table are for Recombivax HB or Engerix-B.

^bRecent CDC recommendations for exposure (sexual, sexual assault, percutaneous, or mucosal) from a source with unknown hepatitis B status are to forgo vaccine and HBIG if the exposed patient is already immunized and has written documentation of complete vaccine series and did not receive serologic testing for response. Individual assessments of potential risk must be made.

^cPeople who have not responded to two vaccine series are discussed in the text.

HBIG, Hepatitis B immunoglobulin; anti-HBs, antibody to hepatitis B surface antigen; HBsAg, hepatitis B surface antigen.

HBsAg-positive materials (e.g., blood, plasma) and for neonates born to HBsAg-positive mothers (see Table 246.3).²⁹

Exposure to blood that contains or may contain hepatitis B surface antigen. No prospective studies have tested the efficacy of a combination of HBIG and hepatitis B vaccine in preventing hepatitis B after accidental exposure, including exposure by the percutaneous, ocular, and mucous membrane routes or by human bites that penetrate the skin. Health care workers at risk for accidents should receive hepatitis B vaccine because preexposure immunization is the most effective means to prevent HBV transmission.²⁹ For unimmunized people, the combination of HBIG and hepatitis B vaccine is recommended after significant accidental exposure (Table 246.4).

If the exposed patient is unimmunized and the blood or secretions come from an individual known to be HBsAg positive or the infection status of the source is unknown but the source is at high risk, immediate prophylaxis is indicated. A single dose of HBIG (0.06 mL/kg or 5 mL for adults) should be given intramuscularly as soon as possible, preferably within 24 hours of exposure.²⁹ Hepatitis B vaccine should be given simultaneously at a different site and repeated after 1 and 6 months (see Table 246.4). After massive exposure (i.e., by blood transfusion), much larger doses of HBIG may be indicated.

If the exposed patient has been immunized but the serologic response is not known, anti-HBs titers should be determined and the individual treated according to the results; if nonresponsive (i.e., anti-HBs <10 mIU/mL by radioimmunoassay), HBIG and a full series of vaccine should be given. For patients with a contraindication to vaccine, two doses of HBIG (0.06 mL/kg) should be used, the second administered 1 month after the first. Two doses of HBIG also should be given to an exposed health care worker who is known to have no response to two series of hepatitis B vaccine.²⁹

The CDC recommendation¹⁴⁸ for nonoccupational exposures is to administer vaccine alone to previously immunized individuals as a booster dose without the need to document serologic response if the exposed person has written documentation of a completed hepatitis B vaccine series. The *Red Book*²⁹ agrees with this booster vaccine approach. I recommend a more individualized approach for assessing risks of the addition of HBIG.

Perinatal exposure. Among mothers who are HBsAg positive and HBeAg positive, 85% of their untreated infants will become infected and be chronic carriers, and chronic hepatitis, cirrhosis, or hepatic cancer will develop in some of them. If the mother is HBsAg positive only, the risk for her offspring of becoming a carrier is less but still significant. More than 90% of infants infected perinatally develop chronic HBV infection.²⁹ These infants should receive HBIG prophylaxis and hepatitis B vaccine.

Infants born to mothers who are HbsAg positive. For optimal passive-active immunity, HBIG (0.5 mL) is given to the newborn at birth (preferably in the delivery room but within 12 hours at the latest). Hepatitis B vaccine (at a dose that is one half of the adult dose) is begun simultaneously and repeated at 1 and 6 months (see Table 246.3). This combination is only about 90% effective in preventing the carrier state because intrauterine infection is not prevented.

Term infants born to mothers not tested for HBsAg. If the HBsAg status of the mother is unknown, hepatitis B vaccine should be given to the term infant within 12 hours, and HBIG should be administered as soon as the mother is shown to be a carrier. Its effectiveness is diminished markedly if administration is delayed beyond 48 hours after birth but is recommended to be given up to 7 days after birth.²⁹

The mother should be tested immediately. If she is HBsAg negative, the vaccine series is continued as recommended for other infants. If the mother is found to be HBsAg positive, HBIG and hepatitis B vaccine should be given to her infant, even if a significant delay has occurred. After the final dose of the vaccine series, the infant can be tested for HBsAg and anti-HBs at 9 to 18 months to determine the success of the HBIG and vaccine regimen. Testing should not be performed before 9 months of age to avoid detection of anti-HBs from HBIG administered during infancy and to maximize the likelihood of detecting late HBV infections.²⁹ If HBsAg is found, the infant is a carrier. If anti-HBs is detected, the child was successfully immunized. Administration of HBIG at birth should not interfere with polio or DTaP vaccines starting at 2 months of age.

Premature infants. Premature infants with birth weights less than 2000 g who are born to women not tested for HBsAg should be given HBIG (0.5 mL) within 12 hours of birth unless the mother's HBsAg

test result can be available within 12 hours and is negative. Immunization should be started immediately and repeated for a total of four doses (rather than the usual three doses) because of the poorer response of preterm infants to the vaccine.²⁹

Sexual exposure to hepatitis B or a carrier of hepatitis B. Sexual exposure (including rape) to an individual who has hepatitis B or is a carrier is an indication for administration of HBIG (0.06 mL/kg intramuscularly; maximum, 5 mL) and initiation of hepatitis B vaccination. HBIG should be given as soon as possible but not after 14 days after exposure. If only HBIG is given, a second dose of HBIG is recommended after 30 days. The CDC¹⁴⁸ also recommends booster vaccine alone in this situation if written documentation is available for a completed hepatitis B vaccine series.

Possible exposure. After possible exposure (e.g., percutaneous, ingestion, sexual) to an unidentified person or body fluid for which the HBsAg status is unknown, the decision to treat with HBIG must be made individually on the basis of the likelihood that the source is HBsAg positive and the seriousness of the exposure. Hepatitis B vaccine should be initiated immediately if the exposed person is not immunized. Current *Red Book* and CDC recommendations²⁹ suggest that in cases of an unknown source, vaccine alone is acceptable for an unvaccinated exposed patient and that no treatment is required if the exposed person has written documentation of previous immunization. I recommend a more individual approach to assess risks.

Ideally, the source subject should be tested for HBsAg positivity; if the results are available within 7 days for a percutaneous exposure and 14 days for a sexual exposure,²⁹ HBIG (0.06 mL/kg; maximum, 5 mL) can be given immediately and again at 1 month if the source is HBsAg positive and the patient did not or could not receive vaccine. When the source subject cannot be tested or the source is likely to be HBsAg positive, HBIG is administered immediately.

If the exposed individual is a high-risk patient (e.g., immunodeficient, immunosuppressed, institutionalized, undergoing hemodialysis) or is in an environment or health care unit for which past environmental control measures have been ineffective, HBIG should be given in addition to hepatitis B vaccine.

HBIG is not indicated on a routine basis after administration of blood transfusions. School or hospital exposure or usual household exposure is not an indication for HBIG, but household exposure is an indication for vaccine for unimmunized exposed individuals.²⁹

Liver transplantation. For patients who are HBsAg positive at the time they undergo liver transplantation or in the rare situation in which the donor of the liver is HBsAg positive, administration of HBIG is recommended in the preoperative period and after transplantation to prevent recurrence in the transplanted liver.^{274,490,603,604,701,703,708}

The typical regimen is to use very high HBIG doses (i.e., 2000 IU [10 mL]/wk) before transplantation and immediately after transplantation along with antiviral medications.⁷⁰³ The HBIG is continued for several months to years, and the dose is determined by monitoring of the hepatitis B viral burden by PCR. After several months, the HBIG dose may be reduced or discontinued, but the antivirals are continued, as discussed earlier.⁷⁷⁷

Hepatitis C

Early studies suggested that lots of polyvalent IGIM or HBIG not screened for hepatitis C antibodies provided some protection against the acquisition of non-A, non-B hepatitis (presumably hepatitis C) after heart surgery or hemodialysis.^{387,607,648}

Two studies provide some evidence for a prophylactic effect of IGIM. Piazza and colleagues⁵⁵⁶ gave polyvalent IGIM (from pools containing antibodies to hepatitis C virus [HCV]) or placebo monthly for 4 to 20 months to the seronegative sexual partners of 884 patients who were seropositive for HCV. One of the 450 (representing 560 subject-years) in the IGIM group became infected, compared with 6 of 449 (500 subject-years) in the placebo group ($P = .03$; relative risk, 10.7). The study authors concluded that sexual transmission of hepatitis C occurs and that immunoglobulin has a protective effect.

Féray and associates²²⁵ reviewed the records of 218 patients with hepatitis C coinfection undergoing liver transplantation who received an HBIG product that contained antibody to HCV. The incidence of

HCV viremia 1 year after transplantation was significantly lower (25 [54%] of 46) among patients receiving HBIG than those not receiving it (162 [94%] of 172; $P < .001$). They also reviewed 210 transplanted HCV-seronegative patients and found that hepatitis C developed within 1 year in 18 (26%) of 68 patients who received the HBIG product containing anti-HCV antibody, in contrast to 40 (47%) of 86 patients who did not receive HBIG, a significant difference ($P < .001$) suggesting a preventive effect of hepatitis C antibodies.

Also supporting this concept was the observation that HCV was transmitted by pooled human immunoglobulin in the early 1990s, shortly after HCV antibody-positive donors were excluded from the donor pool.^{146,614} These antibodies presumably neutralized the small amounts of HCV in the unscreened lots. Yu and colleagues⁷⁸⁸ demonstrated that HCV antibodies in unscreened immunoglobulin lots containing HCV antibodies prevented low-dose infection in chimpanzees. Screened IGIM lots after 1991 lacking HCV antibodies did not prevent infection.

Because HBIG can prevent recurrence of hepatitis B among patients with hepatitis B undergoing liver transplantation,^{274,604} researchers have postulated that hepatitis C antibodies might prevent recurrence in hepatitis C-positive liver transplant recipients. Studies are ongoing to develop monoclonal antibodies, immunomodulators, and vaccines to effectively neutralize HCV.^{12,100,253,369,370,532,748} Bavituximab is a monoclonal antibody that targets phosphatidylserine, a specific phospholipid component of cell membranes that become exposed on the outer membrane of cells infected with HCV. A phase I study demonstrated mild adverse events for six patients.¹²

Experimental Hepatitis C Immunoglobulin

Experimental HCV-IGIV is derived from human plasma units rejected for HBIG or IGIV manufacture because of the presence of hepatitis C antibodies. It does not contain hepatitis C, as tested by PCR. Krawczynski and colleagues³⁹⁷ showed that HCV-IGIV delayed but did not prevent experimental hepatitis C infection in chimpanzees, in contrast to regular IGIV without hepatitis C antibodies.

Willems and colleagues⁷⁶⁶ gave HCV-IGIV to 26 hepatitis C-positive liver transplant recipients during the ahepatic and postoperative periods without decreasing the rate of recurrence of hepatitis C. Davis and colleagues¹⁸⁷ reported a multicenter, double-blind study of HCV-IGIV (Civacir, Nabi) in hepatitis C-positive liver-transplant recipients. No effect occurred on HCV RNA levels, but some decrease in liver enzyme activities compared with control patients was observed. The use of antibody to prevent the development of hepatitis C after liver transplantation has not been successful, which was attributed to limitations of dosing and the inability of HCV-IGIV to neutralize the HCV RNA in phase II trials.¹⁸⁷

Recommendations. No passive immune product is available for hepatitis C prophylaxis.

Herpesviruses

The common herpesviruses that cause human infection are CMV, Epstein-Barr virus (EBV), herpes simplex virus types 1 and 2, varicella-zoster virus, and human herpesviruses 6, 7, and 8. Although these DNA viruses produce latent infection that can reactivate, particularly in immunodeficient patients, the major uses of immunoglobulins have been in the prevention of primary varicella-zoster virus infection and prevention and treatment of CMV infection in transplant recipients and in pregnant women and their fetuses with primary infection.

Cytomegalovirus

Use of cytomegalovirus intravenous immunoglobulin or intravenous immunoglobulin in transplantation. CMV infection remains a major complication after hematopoietic cell transplantation and solid organ transplantation. Seronegative individuals who receive an allograft from a seropositive donor are at the highest risk for acquiring CMV infection. Polyvalent IGIV and hyperimmune CMV intravenous immunoglobulin (CMV-IGIV [CMVIG]) have been used since the 1980s to prevent development of CMV infection in bone marrow and solid organ transplant recipients.⁷⁷⁴ Clinical trials in the 1990s demonstrated the efficacy of prophylaxis with IGIV in preventing CMV infection and

pneumonia. CMVIG is prepared from the plasma of donors with high anti-CMV titers, but polyvalent IGIV also contains anti-CMV antibodies at a lower titer. Early studies used CMVIG or IGIV alone, but later studies have combined immunoglobulin with antiviral agents.

Early studies of renal and liver transplant recipients showed the efficacy of CMVIG or IGIV.⁶⁵⁴ Two meta-analyses demonstrated decreased CMV mortality rates with the use of CMVIG or IGIV in bone marrow and solid organ transplant recipients.⁷⁷⁶ Others have shown a similar prophylactic benefit for IGIV or CMVIG.^{476,639} Ruutu and coworkers⁵⁹⁹ showed no prophylactic benefit for CMVIG in CMV-seronegative bone marrow transplant recipients. A multicenter retrospective review⁵⁷¹ of CMVIG prophylaxis in addition to intravenous ganciclovir in pediatric lung transplant recipients did not demonstrate a decrease in post-transplant CMV infection or morbidity rates.

Several factors that have reduced the need for CMVIG or IGIV in transplant recipients include the realization of a markedly reduced risk for development of CMV if the donor and recipient are CMV antibody negative (D^-/R^-), use of CMV-seronegative or filtered blood products, early detection of CMV by PCR, and use of ganciclovir-valganciclovir prophylaxis or early treatment.²⁹⁷

Snydman and colleagues,⁶⁵³ in an open-label, multicenter study of liver transplantation, found that the combination of CMVIG and ganciclovir was superior to different immunosuppressive regimens in historical controls. Campbell and colleagues¹³² recommended universal prophylaxis for the patients at highest risk, children receiving liver transplants (D^+/R^-), but the role of immunoglobulin was uncertain.

For heart and lung transplant recipients, the use of CMVIG for CMV infection prophylaxis has been recommended by some groups if the donor or the recipient is CMV seropositive. Weill and associates⁷⁵⁴ showed that combined ganciclovir and CMVIG reduced the incidence of CMV infection in high-risk lung transplant recipients compared with historical controls. In a retrospective study, Ruttman and colleagues⁵⁹⁸ showed decreased morbidity resulting from CMV infection in lung transplant recipients given CMVIG and ganciclovir compared with the use of ganciclovir alone. A meta-analysis examining the use of CMV hyperimmune globulin (CMVIG) for the prevention of CMV infection and disease in solid organ transplant recipients demonstrated that prophylactic administration of CMVIG was associated with improved total survival and a reduced frequency of CMV-related disease and deaths.⁹⁹

Zamora and associates⁷⁹² recommended intravenous ganciclovir and CMVIG for all lung transplant recipients when the donor or recipient is CMV seropositive; and in the situation of D^+/R^- . They gave seven infusions of CMVIG in the first 90 days after transplantation. Other investigators^{99,184,725} and consensus statements^{45,561} permit the use of combined therapy with CMVIG for high-risk heart and lung transplant recipients and other solid organ recipients, despite the absence of definitive controlled studies. The use of IGIV for the treatment of hemophagocytic lymphohistiocytosis associated with CMV infection also has been reported.³²⁰

Use of cytomegalovirus intravenous immunoglobulin in perinatal cytomegalovirus infection. Another use of CMVIG may be the treatment of in utero CMV infection.⁵⁰³ Two infusions of CMVIG were given intraperitoneally at 28 and 29 weeks' gestation to a CMV-infected fetus. The therapeutic benefit was unclear because the infant had intracranial calcifications at 2 weeks of age but was free of neurologic symptoms at 1 year of age. Matusuda and colleagues⁴⁵⁸ and Sato and associates⁶¹⁰ used serial anti-CMV immunoglobulin injections into the fetal abdominal cavity to treat acute CMV infection in a fetus with a good fetal outcome.

Nigro and associates⁵⁰⁷ treated a pregnant woman with primary CMV infection and in utero infection of one twin fetus with intravenous CMVIG at 30 weeks' gestation. CMVIG also was injected into the amniotic sac. The affected twin had better growth, decreased placental thickening, and lessened cord edema. Although born with CMV infection and hepatosplenomegaly, the child was normal at the age of 2 years.

Nigro and colleagues⁵⁰⁵ gave 31 pregnant women with primary CMV infection at least one dose of CMVIG (200 U/kg) during pregnancy. Ultrasonic evidence of CMV infection was seen in 15 fetuses. Nine women received additional CMVIG into their amniotic sac or umbilical cord. Only one woman gave birth to an infant with CMV infection,

compared with seven of 14 women who did not receive CMVIG during pregnancy. All of these women had in utero infection confirmed by CMV-positive (culture or PCR) amniotic fluid. The infants of mothers who received CMVIG during the first half of the pregnancy were followed in a case-control study evaluating their outcomes compared with those of 32 congenitally infected infants whose mothers did not receive CMVIG during pregnancy.⁵⁰⁶ The risk for having a CMV-affected child with psychomotor retardation and hearing deficit was significantly higher in the untreated group, leading the study authors to conclude that immunoglobulin administered during the first half of pregnancy to women with primary CMV infection decreases neurologic sequelae associated with in utero CMV infection.

Another group⁷³⁷ compared infected infants born to women with primary CMV infection before 17 weeks' gestation who were treated with 200 U/kg of Cytotect (CMVIG product available in Europe) with those who were untreated and participants in a natural history study. At 1 year of age, four of 31 infants of Cytotect-treated mothers had poor outcome compared with the 16 infants from 37 untreated mothers. Results from a double-blind, randomized, placebo-controlled trial of Cytotect prophylaxis in 124 patients suggested protection against in utero fetal infection (44% in the placebo group vs. 30% in the treated group).⁴⁴⁶ However, treatment with CMVIG did not significantly modify the course of primary CMV infection, and the clinical outcomes were similar for the two groups.⁵⁷⁹

Recommendations. Patients undergoing allogeneic human stem cell transplantation who are at risk for CMV disease (e.g., a CMV-seropositive recipient or a CMV-seronegative recipient and a CMV-seropositive donor) should receive prophylactic antiviral therapy or preemptive antiviral therapy after early detection of infection by CMV PCR. Routine use of CMVIG is not recommended for prevention of CMV disease.⁹⁶

Similarly, for solid organ recipients, the highest risk is a CMV-seropositive donor and a CMV-seronegative recipient, in which case antiviral prophylaxis is used. Antiviral prophylaxis rather than CMVIG or IGIV is used in kidney and liver transplantation.^{342,623} In high-risk situations such as heart and lung transplantation with a CMV-seropositive donor or recipient, some centers use CMVIG in addition to antiviral therapy, despite lack of proof by multicenter, randomized studies.^{99,561,725}

CMVIG or IGIV in combination with antiviral agents is used to treat severe CMV disease, such as pneumonia, in transplant recipients.^{241,533,550,575,790} For CMVIG, 400 mg/kg on days 1, 2, and 7 and 200 mg/kg on days 14 and 21 have been used in addition to antiviral therapy,⁵⁷⁵ although others have used a lower dose (100 mg/kg every other day for 2 weeks).²⁴⁹ IGIV administered as 500 mg/kg every other day for 10 to 59 days, followed by 500 mg/kg once or twice weekly for an extended period, also has been reported.⁵³¹ Garcia-Gallo and colleagues²⁴³ reported the use of CMVIG as an adjunct to antiviral therapy to prevent development of pneumonitis in lung transplant recipients with invasive CMV disease and as preemptive therapy (with ganciclovir) in posttransplant recipients with a persistent CMV viral load.

CMVIG for in utero CMV infection is not recommended routinely, but several studies have demonstrated its safety and efficacy. Its use may be of value in selected situations of confirmed primary maternal infection or fetal infection.

Epstein-Barr Virus

EBV, the etiologic agent of infectious mononucleosis, causes severe infection in immunocompromised patients and males with X-linked lymphoproliferative syndrome. IGIV has been given to EBV-seronegative males with X-linked lymphoproliferative syndrome in an attempt to prevent EBV infection, but EBV infection developed in some of them despite IGIV administration.²³⁰

Transplant recipients with EBV-induced posttransplantation lymphoproliferative syndrome or hepatitis have been treated successfully with a combination of IGIV or CMVIG, antiviral therapy, and IFN- α .^{190,515,696} Ramirez-Arila and associates⁵⁶⁸ studied the concentrations of antibody to EBV in four lots of CMV-IVIG and found that standard EVIG contained higher concentrations of anti EBV antibody than the CMV-IVIG. They also observed that the CMV-IVIG was 1.8 times more expensive than standard IVIG.

A similar approach was unsuccessful in X-linked lymphoproliferative syndrome.⁵²⁵ CMVIG was used in one case because it contains higher titers of anti-EBV antibody than IGIV.¹⁹⁰ One case of fulminant EBV hepatitis was treated successfully with liver transplantation, antiviral therapy, and CMVIG.²²⁴

A multicenter trial indicated that CMVIG given to liver transplant recipients did not prevent posttransplantation lymphoproliferative disease or other EBV disease.²⁷⁶ However, the EBV serology was unavailable for 50 of the 82 donors, hampering interpretation of the results.

Ohta and colleagues⁵²⁴ reported marked improvement of a patient with chronic EBV hepatitis after kidney transplantation by treatment with the anti-CD20 monoclonal antibody rituximab after failure to reduce immunosuppression. Rituximab has been used successfully in the treatment of EBV-induced posttransplantation lymphoproliferative disease in stem cell transplantation^{221,636,683} and solid organ transplantation.^{165,303,310,699,784}

Rituximab also has been used in preemptive therapy in stem cell transplantation based on EBV viral load.^{167,728} Boesch and colleagues⁹⁷ reported the successful use of rituximab to treat an adolescent without immunodeficiency who developed EBV-associated lymphoproliferative disease that involved massive submucosal infiltration of B cells in the lingual tonsils, trachea, and bronchi and resultant near-complete airway obstruction that was unresponsive to steroids. A 28-year-old recipient of an orthotopic liver transplant was successfully treated with antiviral therapy and IGIV for EBV-related posttransplantation lymphoproliferative disease refractory to rituximab.⁷¹² Some centers use IGIV or CMVIG in addition to antiviral therapy as prophylaxis in high-risk transplant recipients.²⁷⁷

Recommendations. Current approaches to EBV-induced posttransplantation lymphoproliferative disease include reduction of immunosuppression and consideration of preemptive therapy or treatment with rituximab,⁶⁵⁷ although antiviral medication, anticytokine therapy, chemotherapy, and immunotherapy all have been used. In a literature review, Giulino and colleagues²⁵⁷ found evidence of a better response to rituximab in children compared with adults and suggested that rituximab might be appropriate as first-line therapy for posttransplantation lymphoproliferative disease in children. The role of IGIV or CMVIG in addition to the use of anti-CD20 monoclonal antibodies has not been clearly defined.

Herpes Simplex Infections

Neutralizing antibody has a protective effect in herpes simplex virus (HSV) infection in the newborn period. Mothers with a reactivated herpes infection during delivery are 10-fold less likely to transmit HSV to their newborn infants during vaginal delivery than are mothers with primary HSV infection at delivery, presumably because of the transplacental transfer of antiherpes antibody.^{30,364} IGIV-containing HSV antibodies have not been used in the prevention of neonatal herpes infection, although Whitley⁷⁶¹ proposed that HSV monoclonal antibody or hyperimmune IGIV should be evaluated for treatment of disseminated neonatal disease.

Maschi and colleagues⁴⁵⁶ compared monthly IGIV (400 mg/kg) with intermittent acyclovir treatment (800 mg twice daily for 1 week each month) in patients with recurrent genital HSV infection for 6 months and found fewer recurrences in the IGIV-treated group.

Recommendations. IGIV is not recommended for the prevention or treatment of HSV infections.

Varicella-Zoster Virus and Varicella-Zoster Immunoglobulin

Immunoglobulin for varicella. After success was achieved with IGIM in the prevention of measles and hepatitis, IGIM was evaluated for the prevention of varicella. Although Funkhouser²³⁸ in 1948 showed some beneficial effects for the use of standard IGIM in the prevention of varicella in an uncontrolled study, Greenberg and colleagues²⁷⁸ and Schaeffer and Toomey⁶¹² were unable to prevent chickenpox in exposed children with IGIM doses of 2.5 to 20 mL.

Others have reported anecdotal evidence for the efficacy of IGIM in large doses during the early stages of chickenpox and herpes zoster. These claims included prompt relief of pain in zoster⁷⁵⁶ and rapid

resolution of skin lesions.^{418,586} However, even high-titer zoster immunoglobulin does not prevent dissemination of herpes zoster.⁶⁶⁷

In 1962, Ross⁵⁹¹ gave 242 children IGIM in doses of 0.1 to 0.6 mL/lb within 3 days of exposure to chickenpox; 209 similarly exposed, uninjected children were used as controls. The attack rate was the same (97%) in both groups, indicating that IGIM does not prevent varicella under these conditions. However, with doses of IGIM above 0.2 mL/lb, the severity of the disease was reduced, as indicated by a decreased number of pox and reduced temperature. Children receiving the largest dose of IGIM (0.6 mL/lb) had maximal temperatures of 38.9°C (102°F) compared with 41.1°C (106°F) for controls and had 40 pox compared with 207 for controls. Other investigators have reported similar but uncontrolled observations that immunoglobulin modifies the severity of chickenpox.^{333,713}

Varicella-zoster immunoglobulin for varicella. The prophylactic value of large immunoglobulin doses in decreasing the incidence and severity of varicella led to a trial of high-titer plasma or immunoglobulin preparations to prevent varicella.⁶² They include zoster immunoglobulin (ZIG) and plasma (ZIP) from convalescing zoster patients and varicella-zoster immunoglobulin (VZIG) prepared from high-titer plasma from normal adults.

In 1969, Brunell and associates¹¹⁹ selected convalescing patients with zoster whose complement-fixing antibody titers were 1:256 or greater and prepared ZIG from their plasma; this material had titers considerably higher than did standard immunoglobulin. Exposed children from six families in which chickenpox was occurring were given ZIG or immunoglobulin at doses of 2 mL. In none of six children receiving ZIG did chickenpox develop, whereas it developed in all six children given standard immunoglobulin. No antibody developed in the ZIG-treated group, indicating that the disease was prevented.

Because this dose did not prevent varicella in leukemic children or other high-risk patients, a larger dose (5 mL) was used in a later study to successfully modify or to prevent varicella in eight of nine high-risk children.^{118,116} Severe varicella developed in one child given a less potent preparation of ZIG. These observations were confirmed in two later studies. Judelsohn and associates³⁵⁴ gave ZIG to 56 exposed high-risk children; mild varicella occurred in seven patients and was prevented in the others, most of whom were susceptible as determined by absence of serum antibody. Gershon and colleagues²⁵¹ gave ZIG to 15 seronegative, high-risk exposed children; varicella was severe in one, mild in nine, and subclinical in five. Subclinical infection was determined by the acquisition of membrane antibody as detected by fluorescent microscopy.

Orenstein and associates⁵³⁰ studied 553 exposed, high-risk patients who received ZIG of two different titers ($\geq 1:1280$ vs. 1:2560). They found that the clinical attack rate after receipt of ZIG correlated with the type of exposure (i.e., varicella developed in 36% with household exposure, 7.7% with hospital exposure, and 0% with school exposure), the rise in antibody titer (i.e., 45% of patients without a fourfold titer increase became ill in contrast to 22% of patients with a fourfold or greater rise in titer), and the titer of the administered ZIG (i.e., significantly more complications and deaths occurred in recipients of the lower titer ZIG).

Because of the limited supply of ZIG and ZIP, VZIG from normal adults became the commercially available product in the United States. Zaia and associates⁷⁹¹ compared the efficacy of ZIG and VZIG in immunocompromised children exposed to varicella. Varicella attack rates and the clinical severity in recipients of VZIG and ZIG were not significantly different. A higher incidence of subclinical infection was indicated by the rise in antibody titer in ZIG recipients (31.3%) compared with that in VZIG recipients (16%). A larger dose of VZIG (2.5 mL/10 kg vs. 1.25 mL/10 kg) reduced the frequency of subclinical infection from 20% to 4.3%. Varicella developed in several high-risk patients with demonstrable serum antibody at exposure, indicating that history-negative, seropositive patients are at risk for clinical varicella-zoster infection and should be given VZIG regardless of antibody titer.

In 2006, VZIG became unavailable and was replaced by VariZIG (available through FFF Enterprises: 800-843-7477, <http://www.fffenterprises.com>), which is similar to VZIG. It is an immunoglobulin product made from human plasma and contains high levels of anti-varicella immunoglobulin and is approved for administration to high-risk

individuals after exposure.^{152,150} IGIV and acyclovir prophylaxis are reasonable alternatives for postexposure prophylaxis if VariZIG is not available.

Intravenous immunoglobulin for varicella prophylaxis. In 1984, Paryani and colleagues^{542,543} observed that IGIV at doses of 4 mL/kg to 6 mL/kg resulted in serum varicella-zoster virus antibody titers comparable to those in patients receiving VZIG at standard doses. Subsequently, Chen and Liang¹⁵⁹ demonstrated that varicella was prevented by a single dose of IGIV at 200 mg/kg in five children with leukemia.

Immunocompromised patients who are receiving IGIV at 400 mg/kg are thought to be protected for 3 weeks after infusion and do not require additional VZIG on exposure.⁴⁰ However, Ferdman and Church²²⁶ reported that varicella occurred in two patients (one was a 21-year-old woman) receiving 500 mg/kg of IGIV after exposure to varicella 7 and 11 days after infusion. Another child receiving 400 mg/kg IGIV developed varicella 9 days after infusion. Both had mild disease and responded well to acyclovir. The investigators suggest that for patients with profound immunodeficiency, VZIG can be given in addition to IGIV.

Kavaliotis and associates³⁶⁹ found that an IGIV dose of 1 g/kg given within 6 to 24 hours of exposure was 90% effective in preventing varicella in an oncology unit, with no additional advantage observed with administration of VZIG. All of the children who contracted VZV received prophylactic treatment consisting of a single infusion of varicella-zoster immunoglobulin (VZIG) at a dose of 1 mL/kg (group A) or intravenous immunoglobulin (IVIG) at a dose of 1 g/kg (group B) or VZIG plus IVIG at the previously described doses (group C).

Tokat and colleagues⁷⁰⁹ described a 32-year-old man with severe varicella pneumonia that progressed to acute respiratory distress syndrome. IGIV (400 mg/kg for 5 days) was given with a successful outcome.

Recommendations. The decision to administer VariZIG or IGIV or acyclovir to prevent chickenpox is based on the patient's susceptibility, the type of exposure, and the patient's immune competence.

Determination of susceptibility. With the exception of bone marrow transplant recipients, most immunocompromised individuals with previous varicella infection are considered immune; however, their immune status should be confirmed with varicella antibody titers. Healthy adults reared in the United States are considered immune if they have a history of varicella, zoster, or vaccination. Immunocompromised children and adults without a history of varicella are considered susceptible because of their higher risk of severe infection. Bone marrow transplant recipients are considered susceptible regardless of the varicella history of the donor or recipient. If varicella or herpes zoster⁴⁵³ develops after transplantation, the patient then is considered to be immune.^{145,721}

An immunocompromised, unimmunized child without a history of chickenpox is considered susceptible even if antibody titers are present because receipt of blood products containing immunoglobulin may result in transient seropositivity. Alternatively, patients who received VariZIG may have had asymptomatic varicella with the subsequent development of varicella antibodies, but they may not be protected on reexposure.²¹ The value of antibody titer to determine susceptibility in these patients is controversial. However, oncology patients who have been vaccinated for varicella before illness and have been seropositive for varicella antibodies before receipt of blood products are considered immune and do not routinely need VariZIG. The severity of immune compromise is also a factor, and bone marrow transplant recipients are considered susceptible despite prior history of immunization or disease.

VariZIG is not recommended for immunodeficient patients who have been vaccinated in the past, provided they previously were shown to have varicella antibody, even if they are seronegative at the time of exposure. These individuals are expected to have mild disease.⁷²¹ Verifying varicella immunity with antibody before forgoing VariZIG administration in this situation is a reasonable approach because administration of VariZIG can be delayed up to 10 days and remain efficacious.

Type of exposure. Individuals residing in the same household as a patient with varicella, people who have had face-to-face contact with a patient considered infectious, and patients sharing the same hospital room are considered to have significant exposure. Because the duration of exposure that results in transmission is not known, each exposure must be evaluated individually. Contact with a varicella vaccine recipient

BOX 246.3 Candidates for Varicella-Zoster Immune Globulin (VariZIG) After Significant Exposure

- Immunocompromised children without a history of varicella and without documented response to immunization^a
- Susceptible, pregnant women
- Newborn infants whose mothers had an onset of varicella within 5 days of delivery or within 48 hours after delivery
- All hospitalized premature infants born at <28 weeks' gestation or <1000 g at birth, regardless of maternal history
- Hospitalized premature infants of >28 weeks' gestation whose mothers have no history of chickenpox or who are seronegative; may consider its use for other premature infants

^aSeverity of immune compromise is a factor in the decision to give VariZIG despite immunization and disease history.

with a varicella rash must be considered a significant exposure for an immunodeficient patient because the vaccinee may have wild-type virus infection; vaccine strain virus rarely has been transmitted.¹⁴⁵

Candidates for varicella-zoster immunoglobulin or intravenous immunoglobulin.

Normal adults, children, and adolescents. Normal children, adolescents, and adults exposed to chickenpox or zoster usually are not candidates for receiving VariZIG or IGIV (Box 246.3). Because of the prolonged incubation period for varicella, the chickenpox vaccine can be given if the exposed individual is older than 12 months.

Immunocompromised children and adults. The principal use of VariZIG is to prevent chickenpox in susceptible immunocompromised children exposed to zoster or chickenpox (see Box 246.3). This group includes those with primary immunodeficiency and those with secondary immunodeficiency, including HIV infection and neoplastic disease, and those receiving immunosuppressive therapy (e.g., systemic steroids, chemotherapy).^{51,517,530} Susceptible pregnant women are also candidates for VariZIG because of their increased risk of severe varicella pneumonia.^{68,416,652}

Term and premature newborns. Newborns who acquire varicella after birth are not at high risk for severe disease and are not candidates for receiving VZIG, with the possible exception of those whose mothers have severe skin disease.⁴¹⁶ Newborn infants born to mothers in whom varicella developed within 5 days before or 2 days after delivery are at high risk for severe varicella because they have not received transplacental protective antibodies.⁷²¹ Others, questioning the validity of these limits, have treated a small number of infants born to mothers in a window ranging from 7 days before delivery to 5 days after delivery with IGIV (500 mg/kg) and a prophylactic acyclovir regimen.³²⁵

Exposed hospitalized premature infants born at less than 28 weeks' gestation or less than 1000 g should receive VariZIG. These infants are susceptible, regardless of the maternal history of varicella, because of incomplete transplacental transfer of maternal antibody. Hospitalized premature infants with significant exposure who were born at more than 28 weeks' gestation and whose mothers do not have a history of varicella or are seronegative also are considered candidates for receiving VariZIG because transplacental antibody would not be present.^{416,453,721}

Gold and colleagues²⁶² showed that gestational age of more than 28 weeks and birth weight above 1000 g do not always accurately predict the presence of maternal varicella antibody. Ogilvie⁵¹⁷ suggested that infants born before 30 weeks' gestation be given VariZIG and that some infants born after 28 weeks will lose their maternal antibody by 60 days of age. She recommends antibody testing on exposure if it can be performed quickly to assess the need for passive immune prophylaxis. Linder and colleagues⁴³⁰ also found that only 24% of premature neonates born at 29 to 35 weeks had positive fluorescent antibody to membrane antigen (FAMA) titers at 2 months of age.

Gold and associates²⁶² recommended the routine use of VariZIG in the neonatal ICU if the FAMA assay is not available to determine susceptibility. Previous administration of blood products in the neonatal ICU may render these results uninterpretable.

Dosage. The VariZIG brand of VZIG is supplied in lyophilized vials of 125 U (reconstituted to a 5% solution for intramuscular use). The dose of VariZIG is 125 U/10 kg given intramuscularly. The minimal dose for infants is 125 U (one vial), and the maximal dose is 625 U for adults (five vials).^{38,151}

Although VariZIG should be given to susceptible candidates as soon as possible after exposure for maximal protection, it can be given up to 10 days after exposure.^{138,150} A second dose is not needed for subsequent exposure unless it occurs beyond 3 weeks after administration of the VariZIG dose.²¹ IGIV (400 mg/kg) is an acceptable alternative if the child has a bleeding diathesis and cannot receive intramuscular injections or VariZIG is not available.⁷²¹

VariZIG is not recommended for the treatment of chickenpox, zoster, disseminated varicella, or postherpetic neuralgia. Zoster immunoglobulin did not prevent dissemination of zoster in immunocompromised patients.⁶⁶⁷

Human Immunodeficiency Virus Infection

The rationale for use of IGIV in patients with advanced HIV disease is their increased susceptibility to common bacterial and viral infections, poor primary antibody responses to vaccine antigens despite hypergammaglobulinemia, and in young children, a limited antibody spectrum to common bacterial pathogens. Although the central immune defect in acquired immunodeficiency syndrome (AIDS) is a loss of helper T-cell (CD4⁺) number and function, the polyclonal B-cell activation and defective helper T-cell function result in a significant B-cell deficiency.^{83,512}

In children with AIDS, bacterial infections occur more commonly than opportunistic infections. Immune-mediated thrombocytopenic purpura and viral diseases (i.e., RSV, parvovirus, and other disorders amenable to IGIV prophylaxis or therapy) also can develop in patients with AIDS.

After preliminary uncontrolled studies suggested a benefit for IGIV in children with advanced HIV infection,^{131,641} two large, multicenter, controlled studies undertaken by the National Institutes of Health–supported Pediatric AIDS Clinical Trial Group determined the efficacy of IGIV in decreasing infections and improving survival in AIDS patients.^{500,661}

In the first study, 372 children received 400 mg/kg of IGIV every 4 weeks or an albumin control for 2 years.⁵⁰⁰ Thirty percent of all children in the IGIV-treated group had serious infections in contrast to 42% in the placebo group. Children who were less ill (i.e., those with CD4⁺ lymphocyte counts >200 cells/mL) benefited in particular from IGIV. Children in this category had fewer serious infections and were hospitalized less frequently than those in the placebo group, and their CD4⁺ counts dropped less rapidly than those of the placebo group.⁴⁸³ The mortality rate for both groups was identical. Children with CD4⁺ counts less than 200 cells/mL (i.e., those with severely impaired immunity) who were given IGIV had no significant decrease in infections, days of hospitalization, or deaths compared with their counterparts in the placebo group.

The study authors concluded that IGIV significantly reduced the risk of serious infection for some children with symptomatic HIV infection, primarily those with CD4⁺ counts between 200 and 500 cells/mL. In a follow-up study, the placebo group was allowed to cross over to receive IGIV, with a drop in the rate of serious infections and hospitalizations.⁴⁸⁶

In a second trial of IGIV in which all the children received zidovudine, a significant decrease in serious bacterial infections was found, but this benefit was limited to children who did not receive trimethoprim-sulfamethoxazole prophylaxis for *Pneumocystis jiroveci* pneumonia.⁶⁶¹ The consensus of an HIV Working Group⁷⁸⁰ was that HIV-infected children with significant hypogammaglobulinemia or documented poor antibody formation might be candidates for receiving IGIV therapy. IGIV also may be beneficial for HIV-infected children who have recurrent infections not controlled by antibiotics or chronic nonspecific diarrhea with failure to thrive. IGIV also was shown to prevent serious infections in adults with advanced HIV infection.³⁸²

In addition to preventing serious bacterial infections, IGIV given to children with HIV infection reduced the number of nonserious

bacterial infections (by 60% for ear infections, 13% for skin infections, and 10% for other upper respiratory tract infections) and viral infections by approximately one third in both trials.^{480,484,482,661} In an additional study, 135 children with symptomatic and asymptomatic perinatally acquired HIV infection in addition to uninfected infants were given monthly IVIG infusions over 12 months. The study authors found significant reductions in the frequency of common bacterial infections in the HIV-symptomatic group compared with the asymptomatic and the control groups.⁵²⁶ Another study showed that monthly IGIV could be safely discontinued in children who are clinically stable and receiving highly active antiretroviral therapy (HAART).²⁸⁰

Regular IGIV infusion improved left ventricular function in HIV-infected children with dilated cardiomyopathy.⁴³² It is also effective in treating certain other complications of HIV infection, including thrombocytopenia,^{129,410} red cell aplasia associated with parvovirus B19 infection,³⁹¹ Guillain-Barré syndrome,²⁵⁶ and certain drug reactions.²²⁹

IGIV, even in high doses, provides no antiviral activity in HIV infection.⁵²⁸ Attempts to use HIV-specific antibody to prevent HIV infection or to provide an antiviral effect have met with very limited success.

These studies have used human immune plasma or hyperimmune HIV immunoglobulin (HIVIG) from asymptomatic HIV-seropositive patients, porcine antisera, or monoclonal antibodies.⁶⁷⁴ In two of three controlled clinical trials of immune plasma in adult patients with AIDS, a modest clinical benefit was achieved, as judged by decreased opportunistic infections, a slight increase in CD4⁺ cell counts, and improved survival. However, no striking decreases in viral burden were seen.^{337,424,740}

In a double-blind, placebo-controlled, multicenter study, HIV-seropositive pregnant women receiving zidovudine were given HIVIG monthly during the last trimester of pregnancy, and their newborns were given one HIVIG dose at birth. No effect on the rate of maternal-fetal HIV transmission compared with that in a similar group given regular IGIV was found.⁶⁷³ The rate of transmission in both groups was unexpectedly low (<5%), and the study was discontinued after 800 patients had been enrolled because the study was not statistically powered to detect a slight reduction in transmission rates.

Another study examined the antiviral effect of large doses of HIVIG in 30 children with moderately advanced HIV infection who were receiving stable antiviral treatment and showed a measurable viral burden.⁶⁷² No striking beneficial effect was observed as indicated by plasma HIV RNA levels, cellular viral culture titers, or immunologic assays.

Despite these failures, efforts to develop antibody preparations that can neutralize the virus continue. These preparations would be particularly valuable after needlestick, perinatal, or sexual exposure.⁶⁷² Under study are monoclonal antibodies to neutralizing regions of the virus, antibodies to coreceptors that may interfere with HIV attachment, and combinations of antibodies with different specificities, including combinations of HIVIG with monoclonal antibodies.^{47,126,409,427,428,538} An effective neutralizing antibody also would provide valuable information toward an effective vaccine.

Recommendations. IGIV may be beneficial in symptomatic children with HIV infection to prevent bacterial and viral infections and treat certain complications (e.g., thrombocytopenia, anemia of parvovirus infection, and autoimmune hemolytic anemia [Duncan syndrome]), but it has no direct antiviral activity. Because the administration of HAART plays a critical role in the reconstitution of the immune system, specifically the cellular immune system and resultant increase in humoral immunity, additional passive immunity administered with IGIV has not had a substantial benefit for children with well-controlled HIV infection. HIVIG or plasma derived from infected patients has little or no antiviral activity or clinical benefit for HIV-infected adults or children, and the administration of HIVIG during pregnancy did not provide added reduction in maternal-fetal transmission of HIV.

Measles

The first successful prophylaxis of measles with convalescent serum was reported by Cenci in 1907.¹¹⁸ Convalescent serum was used in the United States first in 1916 by Park and Freeman⁵³⁹ and Zingher,⁷⁹⁸ who

gave 4 or 8 mL of serum to 41 recently exposed children at New York Metropolitan Hospital. Measles did not develop in any of the 20 children who received the 8-mL dose and developed in only 3 of the 20 children who received the 4-mL dose. In 1926, Park and Freeman⁵³⁹ found that 6 to 10 mL of convalescent serum was 92% efficacious in preventing measles in recently exposed individuals, a finding confirmed and extended by Stillerman and associates.⁶⁷⁵ Placental extracts containing serum antibodies also were used in the prevention and modification of measles.⁴⁶⁶

Stokes and colleagues⁶⁷⁹ and Ordman and associates⁵²⁹ confirmed in 1944 that immunoglobulin given immediately after exposure could prevent or modify measles, and given in the early stages of clinical illness, it could lessen its severity. In 1955, Greenberg and coworkers⁵⁷⁹ observed that a lower incidence of measles encephalitis in IGIM-modified measles.

A major use of IGIM in the 1960s was to diminish the side effects of the Edmonston strain of measles vaccine. In 1962, Krugman and associates⁴⁰³ observed that the simultaneous administration of 0.02 mL/lb of immunoglobulin at the time of Edmonston measles vaccination reduced the incidence of high fever from 40% to 14% and the incidence of rash from 10% to 2%. The mean titer of measles antibody achieved was somewhat reduced by the IGIM, and a slight decrease in the rate of seroconversion occurred; nonetheless, the vaccine and IGIM combination was 95% effective.⁶⁷⁸ The current measles vaccine is less reactogenic and does not require concomitant IGIM injections.

Audet and colleagues⁵⁵ report that the measles neutralizing antibody titer in recent IGIV lots is decreasing because of the lower titer of vaccine-induced antibodies compared with natural infection among donors. Although not tested, IGIM probably has lower titers of measles antibodies, and the recommended prophylactic doses may be inadequate.

Recommendations. IGIM or IGIV can be given to susceptible contacts within 6 days of exposure to prevent or to modify measles.³¹ Infants younger than 1 year, immunocompromised patients, and pregnant women are at risk for severe disease and should receive immunoprophylaxis. Because HIV-infected patients with significant immunodeficiency may contract measles after exposure despite receiving immunization, they should also receive passive immunoprophylaxis.²⁵⁰ IGIM is not recommended for healthy household or other close contacts if they have received at least one measles-containing vaccine, unless they are immunocompromised. Measles vaccine has some efficacy if it is given within 72 hours of exposure and is preferred for the management of outbreaks among healthy individuals older than 1 year of age.³¹

The standard dose of IGIM is 0.25 mL/kg for healthy patients and 0.5 mL/kg for immunocompromised patients. The maximal dose is 15 mL. IGIV at comparable doses also can be used, but titers may be diminished in recent years.⁵⁵

Immunodeficient children receiving regular IGIV treatments at doses of at least 400 mg/kg should be protected for up to 3 weeks after administration.³¹ Administration of IGIM to a healthy infant precludes the use of measles vaccine for 5 months if the dose was 0.25 mL/kg and 6 months if the dose was 0.5 mL/kg. For larger doses, longer intervals are needed (e.g., 8–11 months).³¹

IGIV in addition to other immunomodulators has been used for the treatment of acute measles infection⁴⁹⁵ and subacute sclerosing panencephalitis (SSPE), a delayed, rare, degenerative neurologic disease complicating wild-type measles infection.²⁶⁶

Mumps

Mumps immunoglobulin has limited efficacy as postexposure prophylaxis, and this product no longer is manufactured in the United States.^{32,174}

Parvovirus

Human parvovirus B19, also called erythrovirus, is the cause of the benign childhood exanthem called fifth disease. It may also cause polyarthropathy, transient aplastic crises in patients with hemolytic anemia, chronic red cell aplasia in immunocompromised patients, and hemophagocytic syndrome.^{112,331,786} Patients susceptible to chronic parvovirus infection include those with congenital¹⁷⁰⁰ or acquired immunodeficiencies,^{166,391} those receiving immunosuppressive therapy,^{220,786} and organ transplant

recipients.^{363,451} In utero parvovirus infection can result in hydrops fetalis.⁷¹¹ The use of parvovirus DNA PCR has facilitated establishment of the diagnosis in immunodeficient patients unable to make antibodies or in patients who have passively acquired parvovirus antibodies.

Parvovirus B19 has tropism for marrow erythroid progenitor cells because the cells express the blood group P antigen, the cellular receptor for the virus. Because most adults have encountered and made antibodies to parvovirus, IGIV is an excellent source of anti-parvovirus B19 antibodies.⁶¹⁹ IGIV has been used successfully to treat parvovirus-induced red cell aplasia.^{179,411} Successfully treated patients have decreased viremia, reticulocytosis, and resolution of the anemia within 2 weeks. Sometimes, relapse or persistent infection occurs, requiring maintenance IGIV therapy, particularly in patients with HIV infection and low CD4⁺ cell counts.³⁹⁰

For treatment of chronic infection in immunodeficient patients, IGIV therapy often is effective and should be considered.^{33,227} IGIV has been used successfully to treat parvovirus B19 anemia resulting from chemotherapy⁴⁶⁸ or rituximab therapy,⁶³¹ or both.^{336,658} However, IGIV was not of value in four children with persistent parvovirus infection undergoing chemotherapy for acute lymphocytic leukemia.²²⁷ IGIV also has been used successfully for treatment of parvovirus B19 anemia in renal transplant recipients.^{163,452,534,655}

Viguier and coauthors⁷³⁶ administered 1 g/kg of IGIV for 2 days to treat successfully a 33-year-old woman with parvovirus B19–associated polyarteritis nodosa and fever, palpable purpura, intense myalgia, paresthesias, and polyarthritides of the hand joints. IGIV has been used with success in parvovirus B19–associated chronic fatigue syndrome in three adults³⁷⁹ and one teenage boy.⁴⁶⁵

IGIV has been used as a supplement to transfusions in severe in utero parvovirus infection with hydrops fetalis. Selbing and coworkers⁶²² described a 24-week pregnant woman with severe preeclampsia whose fetus had ascites and pericardial effusion. She was given 25 g of IGIV, with resolution of the ascites, effusion, and anemia. Matsuda and colleagues⁴⁵⁹ treated a parvovirus B19–infected hydropic fetus with two injections of immunoglobulin into the fetal peritoneum, with resolution of the anemia and the hydrops.

Rugolotto and colleagues⁵⁹⁵ treated an anemic newborn due to intrauterine parvovirus infection with IGIV (1 g/kg every 3 weeks for 8 months). Heegaard and coauthors³⁰⁵ reported similar success with IGIV in addition to in utero transfusions. Earlier attempts to treat older infants with persistent parvovirus-induced congenital anemia with IGIV were unsuccessful.¹¹⁴

Dennert and colleagues¹⁹¹ performed a pilot study on the use of IGIV for 17 patients with chronic dilated cardiomyopathy and a significant parvovirus B19 viral load. Endomyocardial biopsies demonstrated a significant reduction in viral load and improvement in cardiac function. IGIV has also been used to successfully treat fulminant hepatitis resulting from parvovirus B19 in a 2-year-old Chinese boy.¹³⁴

Human neutralizing monoclonal antibodies have been generated from infected individuals²⁵⁴ for possible future therapeutic use.

Recommendations. Red cell aplasia caused by parvovirus infection in immunodeficient patients, including those with HIV infection, should be treated with IGIV (400 mg/kg per day for 5 days or 1 g/kg per day for 2 days).^{112,391,489} If relapse is likely to occur because of the patient's severe immunocompromised status, IGIV (400 mg/kg) can be given every 4 weeks.

Neonates with persistent congenital anemia caused by parvovirus B19 should receive IGIV (400 mg/kg) for 5 days, with additional doses given if the anemia does not resolve. Pregnant women carrying fetuses with in utero hydrops fetalis caused by parvovirus B19 infection also may be candidates for IGIV therapy, as discussed in the Parvovirus section.

Rabies and Rabies Immunoglobulin

Rabies is the ideal disease for passive immunization because the exact moment, the exact source, and the exact location of exposure usually are known. The long incubation period and the fact that the virus remains localized to the wound for several days enhance the effectiveness of passive immunization. Although a rabies serum was prepared initially in 1889 by Babes and Lepp,⁵⁶ experiments of Habel²⁹⁴ in mice, guinea

pigs, and monkeys involving the use of rabbit hyperimmune serum demonstrated that antibody worked by two mechanisms: neutralizing the virus while it is still in tissues and retarding the spread of virus within the nervous system, thereby prolonging the incubation period and permitting active immunity by vaccine to become established.

On the basis of these studies, a World Health Organization (WHO) Expert Committee in 1950 recommended that a field trial of the efficacy of hyperimmune rabies serum in conjunction with vaccine be conducted.²¹⁶ It was undertaken in Iran because multiple bites by a single rabid wolf coming into isolated villages occurred, and this severe exposure had an associated 40% to 50% mortality rate. In 1954, a single rabid wolf bit 27 individuals, 17 of whom were bitten on the head. These 17 were divided into three groups: five received vaccine alone, seven received vaccine and one dose of antirabies serum, and five received vaccine and two doses of antirabies serum.⁶⁶ Of the five people treated with vaccine alone, three died of rabies; one in seven in the one-dose antiserum group died, and none of the five in the two-dose antiserum group died.

Antibody studies conducted on these patients indicated that a single or double dose of antiserum, followed by 14 to 21 daily doses of vaccine, resulted in significant levels of circulating antibody for as long as 50 days.²⁹⁵ The antibody found early is supplied passively; after the tenth day, the antibody present is a result of the vaccine. Optimal treatment requires passive and active immunization.

Before 1971, the only available antiserum was of equine origin. It is still the only product available in some countries. Since 1971, human rabies immunoglobulin (RIG) has been available in the United States and many other countries and is preferred because of the lessened risk of serum reactions.⁶⁴² Human antibody has a half-life in the circulation twice that of equine antibody, and higher levels of passive antibody are maintained. However, the antibody response to the vaccine given concomitantly is suppressed more effectively.⁴³³

A case of fatal rabies was reported in a 19-year-old man bitten on the finger by a rabid mongoose despite the recommended postexposure prophylaxis (i.e., RIG and five doses of human diploid cell rabies vaccine).⁶³⁵ Possible reasons for failure included inadequacy of the recommended dose of RIG; vaccine injection into the gluteal region, where more fat is found than in the recommended deltoid region; and decreased antibody response to the vaccine as a result of a possible immunodeficiency state.

Prevention of rabies consists of three essential components: thorough washing of the wound with a 20% soap solution followed by irrigation with povidone-iodine,^{89,597} passive immunization with rabies antibody, and active immunization. Although most cases of failure are caused by lack of adherence to these three strategies,⁵⁵⁷ isolated cases of rabies occurring despite appropriate management have been reported.

Wilde and associates⁷⁶⁵ reported failure of prophylaxis in five Thai children who received multiple bites on the face and head. They suggested that failure to infiltrate all wounds with RIG and surgical closure before the wound was infiltrated might have been factors. Hemachudha and coauthors³⁰⁷ reported failure of prophylaxis in a child with minor scratches on the nose and in a woman with a deep wound on the cheek. They suggested that direct inoculation of virus into nerve endings might have occurred.

Goudsmit and associates²⁶⁷ found that a human monoclonal antibody combination was equivalent to RIG when it was used with vaccine in a hamster model of rabies. Bakker and colleagues^{59,60} reported clinical data from two phase I studies evaluating the monoclonal antibody cocktail CL184 against rabies for use in resource-limited areas where there is no access to human or equine rabies immunoglobulin.

Two phase II trials have been completed in the United States and the Philippines. A third is being conducted in India.^{103,261}

Recommendations. Human RIG is recommended for nonimmunized individuals for all bites by animals in which rabies cannot be ruled out and for nonbite exposure to animals proved to be or suspected of being rabid.^{31,141} Treatment should be given as early as possible after exposure and followed by vaccine administration. The decision to administer postexposure prophylaxis should be based on guidelines.³⁴

Two human RIG products are available in the United States: BayRab and Imogam Rabies-HT. Both are prepared from the plasma of hyperimmunized donors. The recommended dose of 20 IU/kg of RIG must not

be exceeded because higher doses can suppress immunologic response of the simultaneously administered vaccine. The entire dose of RIG should be infiltrated around the wounds as soon as possible after the bite.⁴⁹⁸ If this is not anatomically feasible, any remaining RIG should be given intramuscularly.³⁴

Wilde and colleagues,⁷⁶⁵ recognizing the difficulty in infiltrating multiple wounds with a small volume of RIG, suggested dilution of the RIG. The WHO⁷⁸¹ recommends dilution of the RIG twofold to threefold in saline to ensure an adequate volume for infiltration. RIG should not be frozen, and if it is frozen, it should not be used. In addition to passive immunization with RIG on the first day of treatment, exposed patients should receive active immunization with rabies vaccine in four doses over 2 weeks.

Purified equine RIG—containing rabies antibodies may be available outside the United States and is associated with a low rate of serum sickness (<1%). Equine RIG is administered at a dose of 40 IU/kg, and desensitization before administration may be required.

Administration of one of the three vaccines licensed in the United States should be started at the same time as RIG; however, the vaccine and RIG should not be administered in the same syringe or with the same syringe or needle. Only two of the licensed vaccines are produced and available in the United States: human diploid cell rabies vaccine and purified chicken embryo cell vaccine. The vaccines are equally effective and administered in multiple separate doses. Vaccine should be given in the deltoid muscle or, for an infant, in the anterolateral aspect of the thigh and at an anatomic site removed from the injury or injection sites of RIG. The vaccine should be administered on days 0, 3, 7, and 14 after exposure, with day 0 designated as the day of initial presentation. This new schedule replaces the previously recommended schedule that included a fifth dose administered on day 28.³¹

If RIG is not available immediately, immunization should be started and RIG given if it is available within 7 days.^{34,141,498} If vaccine is not available immediately, RIG should be administered and the vaccine given as soon as possible. If both RIG and vaccine are delayed, both should be given whenever available, regardless of the interval between exposure and treatment.^{34,141,498}

The administration of passive antibody can inhibit the response to rabies vaccines; therefore, the recommended dose should not be exceeded. Vaccine never should be administered in the same parts of the body or with the same syringe used to give RIG. Hypersensitivity reactions to RIG are rare.

RIG is not recommended for patients who previously received a full postexposure vaccine course of human diploid cell rabies vaccine, rabies virus adsorbed, or purified chicken embryo cell vaccine; those who have received a three-dose preexposure intramuscular series of these vaccines; those who have received a three-dose preexposure intradermal human diploid cell rabies vaccine used in the United States; or those who have been immunized with any vaccine and have a documented rabies titer.^{34,141,498}

Postexposure prophylaxis of immunodeficient patients is problematic. Jaiaroensup and coauthors³⁴⁰ reported poor or nondetectable neutralizing antibody in five HIV-infected patients who received intradermal vaccine and proposed that higher doses of vaccine or additional boosters be considered. Serologic failure of preexposure and postexposure rabies immunizations in children with HIV infection has been reported.^{536,707} The number of doses of rabies vaccine recommended for people with altered immunocompetence has not changed; for these people, post-exposure prophylaxis should be continued and comprises a five-dose vaccination regimen with one dose of RIG.

RIG is not indicated for the treatment of rabies. Hemachudha and colleagues³⁰⁸ described a patient with rabies who developed total limb and facial paralysis after receiving RIG.

Respiratory Syncytial Virus

Acute RSV infection of the respiratory tract is the most common cause of hospitalization of infants and young children and a significant public health expense. For high-risk patients such as premature infants and infants with chronic lung disease, RSV infection can be severe and life-threatening. The observation that passively transferred maternal antibody provided some protection from RSV infection⁵¹⁸ led to the

development of passive immunity products to prevent and to modify the severity of infection. No effective vaccine exists.

Respiratory Syncytial Virus Intravenous Immunoglobulin

The first immune modulator used for the prevention of RSV infection was RSV-IGIV (RespiGam), a 5% polyclonal human IGIV prepared from healthy donors with high RSV-neutralizing antibody titers. RSV-IGIV was licensed in 1996 after studies in high-risk infants demonstrated its efficacy. Groothuis and colleagues²⁸¹ conducted a prospective, blinded, randomized trial at five centers and showed that 58 premature infants who received RSV-IGIV at 750 mg/kg per month during the winter months had a significantly lower incidence of RSV lower respiratory tract disease than that observed in 58 premature control infants who did not receive RSV-IGIV (6.9% vs. 24.1%; $P = .01$). The RSV-IGIV-treated patients also had a lower incidence of moderate-to-severe RSV lower respiratory tract disease ($P = .006$), fewer days of hospitalization ($P = .020$), and fewer days in the ICU ($P = .05$).

Another large, multicenter, double-blind, placebo-controlled RSV-IGIV study⁵⁶³ of 510 infants with prematurity or bronchopulmonary dysplasia demonstrated a decreased number of hospitalizations (13.5% vs. 8.0%; $P = .047$), decreased total number of RSV-related hospital days ($P = .045$), and decreased days with oxygen use ($P = .007$). Use of RSV-IGIV also decreased days of hospitalization for any respiratory illness by 38% and total respiratory illness hospital days by 46%, presumably because of antibodies to other respiratory pathogens. An added benefit of RSV-IGIV prophylaxis was a decreased incidence of otitis media (number of episodes: 0.15 per patient vs. 0.78 per control; $P = .003$).^{301,644}

In 1997, the American Academy of Pediatrics recommended RSV-IGIV for high-risk children with prematurity or bronchopulmonary dysplasia²² but not for infants with cyanotic congenital heart disease^{282,647} because of the risk of serious side effects. RSV-IGIV is no longer available.

Palivizumab

In 1996, palivizumab (Synagis), a humanized IgG1 monoclonal antibody against the fusion (F) glycoprotein of RSV,^{259,682} entered clinical trials. Palivizumab neutralizes type A and type B RSV and is 50 to 100 times more potent than RSV-IGIV.⁶⁰⁶ A multicenter, randomized, double-blind, placebo-controlled study of 1502 high-risk infants (i.e., premature infants and infants younger than 2 years with bronchopulmonary dysplasia) demonstrated the efficacy of 15 mg/kg of palivizumab given intramuscularly every 30 days.³³⁰ It resulted in significantly decreased number of RSV hospitalizations (55%; $P < .001$), RSV hospital days ($P < .001$), and days of oxygen therapy ($P < .001$).

Palivizumab was licensed in 1998. It was the first monoclonal antibody approved for the prevention of an infectious disease. Postlicensure studies have supported its effectiveness.^{551,589,649} Although debate continues about the cost-effectiveness of palivizumab in some countries,^{371,527,688} palivizumab prophylaxis for high-risk infants has become the standard of practice in the United States.²⁴

In 2003, Feltes and colleagues²²³ reported the results of an international, randomized, double-blind, placebo-controlled trial of palivizumab prophylaxis in 1287 children with congenital heart disease. With the use of palivizumab, the study showed a 45% reduction in RSV hospitalizations, a 56% reduction in the total number of hospital days, and a 73% reduction in the total number of hospital days with oxygen. European cardiologists and the American Academy of Pediatrics recommend use of palivizumab for infants with hemodynamically significant heart disease (i.e., uncorrected, partially corrected, or with residual disease), pulmonary hypertension or chronic lung disease, and hemodynamically significant dilated or hypertrophic cardiomyopathy causing cyanosis or requiring cardiac medication.^{38,710}

The use of palivizumab for more than one season has been a concern because of the theoretical risk for side effects resulting from the development of an antibody to the murine component.^{414,510} Null and colleagues⁵¹⁰ found that only one child of 55 receiving palivizumab for a second season developed an anti-palivizumab titer of greater than 1:40. This child had a titer of 1:160 on day 30 that fell to 1:10 on day 120 (i.e., 30 days after the fourth injection), suggesting a nonspecific reactivity. No associated adverse events occurred, and the palivizumab trough concentrations were as expected.

Palivizumab or other RSV antibodies are not indicated for the treatment of RSV infection, although some have used palivizumab for treatment of adult and pediatric patients in high-risk settings.^{158,381,624} In a small pharmacokinetic study, Saez-Llorens and colleagues⁶⁰¹ found that although palivizumab was safe, it had no clinical benefit for previously healthy children with acute RSV infection. Banna and colleagues⁶⁷ successfully used palivizumab and steroid therapy to treat an adult woman with RSV-related pneumonia after stem cell transplantation. An experimental RSV monoclonal antibody (Medi-493), given intravenously, showed no benefit for intubated patients with RSV infection and respiratory failure.⁴⁴⁹ Studies of high-titer monoclonal antibodies may yield different results.^{237,613,624}

Passive Immunity in Respiratory Syncytial Virus Treatment

Although a single dose of 1500 mg/kg of RSV-IGIV was of no benefit in normal and high-risk children with RSV infection,^{587,589} DeVincenzo and associates¹⁹³ gave a single dose of RSV-IGIV (1500 mg/kg) to 11 bone marrow transplant recipients after the onset of RSV infection. All but one patient also received ribavirin. Only one patient died in this group, which compares favorably with historical controls given ribavirin therapy alone.

Ghosh and coworkers²⁵² gave IGIV (500 mg/kg) every other day and aerosolized ribavirin to 14 adult bone marrow transplant recipients with RSV upper respiratory tract infection to prevent pneumonia and death. Infection resolved in 10 patients, pneumonia developed in 4, and 2 died. Aerosolized human IGIV was of no clinical benefit in the treatment of patients with RSV infection.⁵⁸²

Recommendations. Palivizumab is indicated for prevention of RSV infection during the RSV infection season for high-risk premature infants or infants with chronic lung disease.³⁵ The period of prophylaxis should be individualized, depending on the duration of the local RSV infection season.

Candidates for prophylaxis. Certain patient groups are candidates for prophylaxis³⁵:

1. Infants younger than 24 months with chronic lung disease requiring medical treatment in the 6 months before the start of the RSV infection season may benefit from prophylaxis. Two seasons of treatment may be required for some infants who require ongoing medical treatment.
2. Premature infants without chronic lung disease who were born before 32 weeks' gestation may benefit from prophylaxis. For these infants, the major risk factors to consider are gestational age and the chronologic age at the start of RSV season.
3. Infants born at 28 weeks, 6 days; gestation or earlier may benefit from prophylaxis during RSV season when that occurs in the first 12 months of life, whereas infants born at 29 to 32 weeks' gestation may benefit most from prophylaxis up to 6 months of age,³⁵ although decisions should be individualized. After an infant qualifies for initiation of prophylaxis at the start of RSV season, administration of prophylaxis should continue throughout the season and not stop on the basis of the chronologic age.³⁵
4. Premature infants of 32 to 35 weeks' gestation who are 3 months or younger at the start of RSV season, including those born during the RSV season, and have one of two risk factors may benefit from prophylaxis: attends child care in a setting with multiple infants or young toddlers or has one or more older siblings (or other child) younger than 5 years living in the household. Prophylaxis should continue until the infant is 3 months of age.³⁵
5. Infants younger than 12 months during RSV season with congenital abnormalities of the airway or neuromuscular disease may be considered for immunoprophylaxis if their condition compromises handling of respiratory secretions.³⁵
6. Children younger than 24 months with hemodynamically significant cyanotic or acyanotic heart disease may benefit from prophylaxis. Criteria include children requiring medication for congestive heart failure and children with moderate to severe pulmonary hypertension. Children with hemodynamically insignificant heart disease are not candidates for palivizumab. This category includes atrial septal defect, small ventricular septal defect, pulmonic stenosis, mild coarctation of the aorta, and patent ductus arteriosus. Children who have had

surgical correction and do not require medications for congestive heart failure also are not candidates for prophylaxis. After cardiopulmonary bypass, a postoperative dose of palivizumab can be given to maintain protection because decreased levels of antibody have resulted from cardiopulmonary bypass.²²⁴

7. Infants who are severely immunocompromised can be considered for prophylaxis, although there are no studies on which to base a recommendation.

Possible indications. Possible indications for use include the following:

1. Nosocomial outbreaks can be an indication. No data exist to support palivizumab use in controlling an RSV outbreak in a hospital setting. However, palivizumab in addition to implementation of strict isolation practices has been used in this setting and may be of value in aborting a nosocomial outbreak of RSV infection.^{1,178,364,412,644} Current dosing recommendations for outpatients may not be adequate for some hospitalized premature infants.⁷⁸²
2. Patients with cystic fibrosis who are younger than 2 years of age may be candidates for RSV prophylaxis, but no data exist on which to base a recommendation.
3. Older, high-risk infants who received palivizumab the previous season but remain unwell, are immunocompromised, or have recently undergone a procedure such as transplantation or operation may benefit from a second season of palivizumab. This includes immunodeficient infants receiving IGIV because IGIV has only low titers of RSV antibodies.

Dosage and administration. Prophylaxis is given monthly from just before the start of the local RSV infection season until the end of the season. Usually, five injections are given from November to March, but starting earlier or extending into April may be required. It is important to be aware of local outbreak data. If an infant develops RSV infection while receiving prophylaxis, palivizumab should be continued because more than one RSV strain could infect the patient in a single season.³⁵

The dose of palivizumab for prophylaxis is 15 mg/kg per month given intramuscularly. It is supplied in 50- and 100-mg vials. Palivizumab is not indicated for the treatment of RSV infections.

Rotavirus

Several reviews have summarized the role of oral immunoglobulin in the prevention and treatment of rotavirus infection.^{98,186,298,535,755} Its effectiveness varies, in part because of differences in antibody titer in the various products.^{70,204,286,287,315,481,609} Human immunoglobulin has been used to prevent rotavirus infection; Barnes and colleagues⁷⁰ and Pammi and colleagues⁵³⁵ gave human gamma globulin orally to low-birth-weight infants in a nursery in which rotavirus was endemic. Patients given human immunoglobulin had a more attenuated disease than the placebo controls.

Human immunoglobulin has been infused into the duodenum to treat two children with prolonged rotavirus infection.²⁸⁶ One patient responded rapidly, but the other had a prolonged course. Losonsky and coworkers⁴³⁴ gave human immunoglobulin to three immunodeficient patients and demonstrated that it survived passage of the gastrointestinal tract in an immunologically active form.

Pooled colostrum concentrate from hyperimmunized pregnant cows with high titers to several rotavirus serotypes has been used in several studies.¹²² In a controlled study, bovine immune colostrum did not prevent development of symptomatic rotavirus infection in infants, but treated patients had a decrease in the duration of diarrhea.⁷¹⁸ Immune bovine colostrum also was used prophylactically for 2 weeks in 10 infants in a childcare center, with evidence of a protective effect.²⁰⁴

A double-blind, placebo-controlled trial of oral lyophilized rotavirus bovine colostrum in Bangladesh showed that a 4-day course decreased diarrhea, the need for oral rehydration, and viral shedding.⁶⁰⁹ Mitra and associates⁴⁸¹ also showed that cow colostrum⁷¹⁶ significantly shortened the duration of diarrhea and decreased stool output. Hilpert and colleagues³¹⁵ demonstrated that rotavirus colostrum decreased virus excretion in infants with rotavirus diarrhea.

A lactobacillus engineered to express a neutralizing antibody fragment of a llama immunoglobulin (i.e., lactobodies) was given orally to

experimental animals with rotavirus diarrhea. It markedly shortened disease duration, severity, and viral load.^{537,727} A recently licensed vaccine for rotavirus seems safe and effective.³⁶

Recommendations. Because rotavirus infection usually is self-limited, no commercial passive antibody product has been developed, although it would be useful in developing countries. The neutralizing titer of human immunoglobulin probably is not high enough to be consistently beneficial. Oral vaccines may decrease the need for antibody-based therapies.

Rubella

Immunoglobulin rarely is used for prevention of rubella because of its uneven efficacy. Early studies suggested some prophylactic benefit. In 1952, Korn³⁹⁶ showed that one lot of IGIM at a dose of 0.1 mL/lb provided partial protection against the development of epidemic rubella. However, the titers of rubella antibodies varied significantly between lots and did not provide consistent protection.

Studies in epidemic situations have shown that 5 mL of IGIM can prevent development of clinical rubella,²⁷³ but Brody and coworkers¹¹⁰ showed that an IGIM dose of 0.55 mg/kg resulted in a decreased clinical attack rate but also a high incidence of subclinical infection. Military recruits were protected by a 15-mL dose of IGIM administered before exposure.³²¹

Extensive studies on IGIM prophylaxis for rubella conducted by Green²⁷⁵ and Krugman and Ward⁴⁰⁵ did not demonstrate a protective effect of IGIM (0.12 to 0.2 mL/lb). Lundström and coworkers⁴⁴² gave 251 exposed pregnant women 4 mL of convalescent rubella IGIM and 28 exposed pregnant women 24 mL of standard IGIM. Rubella developed in 6 (2.4%) of the 251; three of these six women aborted, and one had an infant with probable congenital rubella. None of the 28 women given 24 mL of standard IGIM contracted rubella. Their subsequent study demonstrated that convalescent rubella IGIM given to pregnant women with clinically manifested rubella did not protect against congenital rubella or lessen the probability of fetal damage.⁴⁴³

Recommendations. IGIM prophylaxis is not indicated for children and nonpregnant adults exposed to an infected contact because of the mildness of the infection. IGIM is not recommended for most exposed pregnant women because the clinical syndrome may be masked and congenital rubella not prevented.

For exposed pregnant women who will not consider abortion if rubella develops, IGIM may have some value in reducing the chance for fetal infection. A dose of 0.55 mL/kg of IGIM given intramuscularly is the recommended dose. However, mothers who have received prophylaxis after exposure have delivered infants with congenital rubella.³⁷ Administration of immunoglobulin eliminates the value of IgG antibody testing to detect maternal infection.

Vaccinia, Variola, and Vaccinia Immunoglobulin

Vaccinia virus is closely related antigenically to smallpox (variola) virus, and immunity to vaccinia virus through vaccination prevents smallpox.⁵⁰² Although smallpox has been eradicated from the world since 1977, the virus exists in a few research laboratories and is a potential weapon in biologic warfare.

Vaccination is still given to members of the military, to some health care workers, and to laboratory workers who handle cultures or animals contaminated with vaccinia virus, some recombinant vaccinia viruses, and other orthopoxviruses (e.g., monkeypox, cowpox). Passive immunization occasionally is necessary after laboratory accidents, inadvertent vaccination of high-risk individuals, and exposure of high-risk individuals to a recently vaccinated individual.

Passive immunization against variola was known as early as 1895, when Hlava and Honl³¹⁶ showed that schoolchildren could be protected from variola by the injection of 3 to 10 mL of serum from a cowpox-immune calf. At the same time, protective human antibodies developed after vaccination, and passive transmission of these antibodies from mothers to infants was demonstrated.⁶⁶⁴ Thereafter, effective prevention of smallpox by well-organized mass vaccination campaigns diminished interest in passive immunization.

Janeway, quoted by Enders,²¹⁰ found neutralizing vaccinia antibody in immunoglobulin in 1944, and Verlinde and Spaander⁷³³ in 1949 found

high titers of the antibodies in convalescent immunoglobulin from recently vaccinated individuals. In 1956, Gispén and associates²⁵⁵ developed a human vaccinia immunoglobulin (VIG) that did not interfere with active immunity, and they proposed its use with vaccine as prophylaxis against vaccinia encephalitis. Human VIG is derived from the plasma of vaccinated donors.¹⁴⁴

The value of human VIG in treating smallpox or disseminated vaccinia is based on the presence of viremia, which leads to secondary dissemination. Administration of neutralizing antibody can prevent or limit the spread of infection and modify clinical expression of the disease.

Studies on the efficacy of VIG in treating smallpox and vaccinia complications were initiated by Kempe and colleagues in 1955.^{62,377} They used a VIG that was prepared from recently vaccinated donors with a neutralizing titer of 1:256 to 1:512, in contrast to titers of 1:16 or 1:32 in standard IGIM. The households of new admissions to the Madras (India) Smallpox Hospital were visited, and alternate family contacts received VIG 0.2 mL/lb for adults and 0.05 to 0.2 mL/lb for children.³⁷⁷ After 25 days, eight cases of smallpox developed in 75 contacts not given VIG, and two cases developed in 56 contacts given VIG, a significant difference. A similar, more extensive study disclosed 21 cases of smallpox (four severe) among 379 contacts serving as controls and five cases of smallpox (none severe) among 326 contacts given VIG.³⁷⁸

Kempe³⁷⁶ reported the results of 300 cases of smallpox vaccination (vaccinia) complications treated with VIGIM, including 62 cases of generalized vaccinia, 132 cases of eczema vaccinatum, 23 cases of vaccinia necrosum, 12 cases of vaccinia encephalitis, and 28 cases of autoinoculation. VIGIM was given prophylactically to 44 eczematoid children requiring smallpox vaccine (0.6 to 1.2 mL/kg). VIGIM did not affect the course of vaccinia encephalitis. Of 28 patients with autoinoculation who received VIGIM, 27 did well. Among the 132 patients with eczema vaccinatum given VIGIM, nine deaths occurred; this 7% mortality rate compares favorably with the usual mortality rate of 30% to 40% associated with supportive care only. All 62 patients with generalized vaccinia who were given VIGIM did well, although four children required a second course.

Of the 23 patients with vaccinia necrosum who received VIGIM, seven died (30%); however, this disease usually is fatal, and immune defects were present in most of the patients.⁶⁹ These results strongly supported the efficacy of VIGIM and subsequently were confirmed by studies in Sweden⁴⁴¹ and the United Kingdom.⁶³²

In 1997, Kesson and coauthors³⁸⁰ reported a severely immunocompromised patient with progressive vaccinia who had inadvertently received a vaccinia melanoma oncolysate vaccination but was successfully treated with VIGIM and ribavirin. Nanning⁴⁹⁶ studied the effect of VIGIM on postvaccinia encephalitis. He gave a placebo or 2 mL of VIG to Dutch military recruits at the time of primary vaccination; three cases of encephalitis occurred among 43,630 vaccinated recruits given VIG, compare with 13 cases among 53,044 recruits in the control group. This 77% reduction is statistically significant.

Intramuscular Vaccinia Immunoglobulin and Intravenous Vaccinia Immunoglobulin

Two types of VIG are now available, VIGIM (for intramuscular use) and IV-VIG (for intravenous use). IV-VIG was approved in the United States in 2005 for specific indications—treatment of infections that involve accidental implantation in the eye (except for isolated keratitis), mouth, or other hazardous areas; eczema vaccinatum; progressive vaccinia; severe generalized vaccinia; and vaccinia in patients with burns, impetigo, varicella-zoster, poison ivy, or severe eczema. Both VIG preparations are prepared from the plasma of vaccinated donors.

IV-VIG used at a dose of 100 mg/kg results in a more rapid and higher antibody peak than does an injection of VIGIM.³¹⁹ The first civilian treated with VIGIV was a woman with vaccinia blepharoconjunctivitis; she also received topical antiviral medication.³²⁴ Another laboratory worker with ocular vaccinia was treated with a single dose of VIGIV.⁴²⁵

IV-VIG is available from CDC under an IND protocol that has guidelines for dosage and administration. The CDC Clinical Consultation Team can be contacted through the Clinicians Information Hotline for VIG requests to treat vaccine-related adverse events (877-554-4625, <http://www.bt.cdc.gov/agent/smallpox/index.asp>).

Recommendations. Complications of vaccination are the usual indications for VIG. They include accidental or intentional vaccination of a patient with a contraindication to the vaccine, autoinoculation of the eye, eczema vaccinatum, severe generalized vaccinia, and vaccinia necrosum.

The initial dose of VIGIM is 0.6 mL/kg. In adults, the dose must be divided and administered over 24 to 36 hours. Repeated doses can be given at 2- to 3-day intervals for vaccine complications until recovery begins, as evidenced by no new lesions. VIG should be given as soon as possible after diagnosis is established.^{8,146}

For unimmunized patients exposed to smallpox, VIGIM in combination with vaccine can be given. A dose of 0.6 mL/kg should be given as soon as possible, preferably within 1 to 3 days.^{8,461,718} Current recommendations from the US Army Medical Research Institute of Infectious Diseases suggest that VIGIM may be of value in postexposure prophylaxis of smallpox when it is given within the first week after exposure and concurrently with vaccination. Vaccination alone is recommended for those without contraindications. Both vaccine and VIGIM should be given if more than 1 week has elapsed since exposure occurred.

The current supplies of VIGIM do not permit its routine use in combination with vaccine for bioterrorism exposure.¹⁴⁶ However, if additional supplies become available, a VIGIM dose of 0.3 mL/kg in combination with vaccine can be used.

Cidofovir also has been used.^{106,107} VIGIM is not indicated for established smallpox, postvaccinal encephalitis, or hypersensitivity and toxic rashes that occur after vaccination. However, the lack of efficacy of VIGIM in the past does not exclude a potential beneficial effect for IV-VIG. The pathogenesis of vaccinia encephalitis is poorly understood and may involve both infection and immune response,³¹⁸ and VIGIV may be beneficial.

Inadvertent vaccination of a pregnant woman occasionally results in fetal complications, with an estimated fetal vaccinia case rate of one case per 10,000 to 100,000 vaccinated pregnant women. Although IV-VIG has not been licensed for this purpose, but it can be offered for use as an investigational product. Some investigators suggest use of IV-VIG if it is given within 10 days of vaccination of a pregnant woman.^{141,497,721}

In ocular vaccinia, VIGIM is contraindicated for isolated vaccinia keratitis because it may increase corneal scarring⁴²⁵ as suggested by animal studies. If additional indications for VIGIM exist, such as conjunctivitis, blepharitis, and eczema vaccinatum, keratitis is not a contraindication for use of VIGIM. Scarring can occur from vaccinia keratitis in the absence of VIGIM treatment. IV-VIG has been used in an experimental rabbit model of vaccinia virus keratitis.¹⁸ In this study, the use of IV-VIG neither exacerbated nor ameliorated the keratitis but did not cause the corneal scarring seen with the use of VIGIM. Topical medications such as trifluridine also are recommended.⁵⁵²

In summary, VIG products appear to be generally safe, with few instances of allergic or adverse reactions. The intramuscular and intravenous products are well tolerated, and because intravenous administration results in a more favorable pharmacokinetic profile than the intramuscular preparation, this may be the preferred product for significant vaccinia exposures. The recommended dosage of VIGIV (Cangene) for the management of severe complications of smallpox (vaccinia) vaccination (indications previously listed) is 6000 U/kg, to be given as soon as symptoms appear.⁴⁴ The intravenous product has clinical advantages over the intramuscular product that include absence of mercury, rapid absorption, and more favorable pharmacokinetics.⁷⁷⁵

IV-VIG at a very high dose was used in the treatment of a smallpox vaccinee with undiagnosed acute myelogenous leukemia who developed progressive vaccinia. The total dose given to this patient was 16,740,000 U over 4 days, with good resolution.¹⁴⁹ The CDC has developed clinical evaluation tools for smallpox vaccine adverse reactions, which are available on their website (<http://emergency.cdc.gov/agent/smallpox/vaccination/clineval>).

Regional Viruses

Argentine Hemorrhagic Fever

Junin virus, the etiologic agent of Argentine hemorrhagic fever (AHF), causes a febrile illness with high mortality rates from vascular or

neurologic complications.⁵⁵⁵ Patients may improve or have severe hemorrhagic or neurologic manifestations (or both) within the first 2 weeks of illness.⁴⁴⁷ Maiztegui and colleagues⁴⁴⁷ found that immune plasma given before the ninth day of illness to 91 patients reduced the mortality rate to 1.1%, compared with a mortality rate of 16.5% for the 97 patients given normal plasma ($P < .01$). Ten of the patients who received immune plasma relapsed with fever and cerebellar signs after several weeks, as did eight others who were not part of the study. The neurologic relapse was self-limited in all but one patient, who died.

With a case-fatality rate of the illness without treatment between 15% and 30%, the use of a live attenuated vaccine has markedly reduced the incidence of AHF.²¹² Present specific therapy involves the transfusion of immune plasma with defined doses of neutralizing antibodies during the prodromal phase of illness.¹⁹ However, alternative forms of treatment are called for because of the current difficulties in early detection of AHF, related to its decrease in incidence, troubles in maintaining adequate stocks of immune plasma, and the absence of effective therapies for severely ill patients that progress to a neurologic-hemorrhagic phase.²¹²

Difficulty in obtaining immune plasma, possible neurologic complications of plasma treatment, and lack of efficacy late in the course of the disease have led to the use of ribavirin, despite its limitation late in the disease.²¹³ An effective, live attenuated viral vaccine is in use, with a protective efficacy of 95% against AHF.^{19,448}

Ebola Infection

Ebola virus, a filovirus, causes severe and often fatal hemorrhagic fever. In March 2014, the largest Ebola outbreak in history occurred in West Africa. This outbreak has spurred research therapies, including monoclonal antibodies^{101,479,580} and vaccines,³²⁷ to treat the disease.³⁸³

Kudoyarova-Zubavichene and coworkers⁴⁰⁶ reviewed the use of hyperimmune goat or equine serum in the prevention and treatment of Ebola infection. Goat hyperimmune serum protects guinea pigs from experimental infection if it is given less than 24 hours before exposure and provides some benefit if it is given within 72 hours after exposure. This product was used for emergency prophylaxis in four patients exposed by laboratory accidents. Mild infection developed in one definitely exposed patient, but Ebola disease did not develop in the other three patients with questionable exposure. All four patients also received recombinant human INF- α_2 . Equine serum has protected baboons from low-dose virus challenge but not cynomolgus monkeys from a high-dose virus challenge.³³⁹ Equine serum given to monkeys on the day of infection and 5 days later did not prevent death.³³⁸

Gupta and coauthors²⁹² reported that a murine polyclonal immune serum protected 100% of normal mice and mice with severe combined immunodeficiency after a lethal challenge. Wilson and colleagues⁷⁷⁰ were able to protect mice with monoclonal antibodies to Ebola glycoprotein for up to 2 days after infection. Parren and associates⁵⁴⁰ were able to protect guinea pigs by giving a human neutralizing antibody up to 1 hour after infection with Ebola virus. Protection of mice by neutralizing monoclonal antibody before and up to 2 days after virus was also shown.⁶⁹⁷ Antibody may be a useful agent in the prevention of Ebola disease. Other human monoclonal antibodies are being developed.^{203,454,455,793}

Recommendations. The use of antibody in the prevention and treatment of Ebola infection has not been proved, but monoclonal antibodies and vaccines are being developed.

Tickborne Encephalitis

Tickborne encephalitis is caused by a flavivirus that is endemic in Russia and eastern and central Europe. Several neurologic syndromes are associated with this infection: febrile headache, aseptic meningitis, meningoencephalitis, meningomyeloencephalitis, and postencephalitic syndrome.¹⁹⁹ Meningoencephalitis is the most severe form, and it can result in death or permanent paresis. Effective vaccines are available^{199,290} and have been successful in dramatically lowering the incidence of this disease.⁴⁰⁸

Passive immunization with a hyperimmune human globulin has been used for postexposure prophylaxis in endemic countries, but it may result in antibody-dependent enhancement of infection.^{386,745} Arras and colleagues⁵⁰ question these case reports in contrast to the large

number of doses of passive antibody given. Günther and Hagland²⁹⁰ contend that hyperimmunoglobulin is not indicated for children younger than 14 years because of concerns that antibody may worsen the disease. The lack of efficacy trials also led to questioning of the use of this product.¹⁰

In 1995, von Hedenström and colleagues⁷⁴² recommended hyperimmunoglobulin for postexposure prophylaxis in addition to immunization. In a review of 656 patients with tickborne encephalitis in southern Germany, Kaiser³⁵⁹ concluded that postexposure prophylaxis with hyperimmunoglobulin was less effective than with vaccine and should be used only when necessary. It is thought that vaccine is the best method for disease prevention.

Acknowledgments

I am grateful to Drs. E. Richard Stiehm and Margaret A. Keller, authors of this chapter in the sixth edition of this book, and Dr. Deborah Lehman, author of this chapter in the seventh edition.

Public Health Aspects of Infectious Disease Control

247

Kathleen H. Harriman • Laurene Mascola

PUBLIC HEALTH AND INFECTIOUS DISEASE CLINICIANS

Infectious disease physicians and other clinicians who provide care for patients with known or suspected infectious diseases play an essential role in infectious disease surveillance and are important public health partners. Systematic infectious disease surveillance is critical in informing disease prevention and control efforts, and public health practitioners rely on clinicians to report cases of infectious disease.

In addition to the routine reporting of reportable infectious diseases, which is essential for public health surveillance, often the first notification to public health authorities of an unusual case or cluster of disease cases is made by an astute clinician. Only after public health authorities are alerted to an unusual case or cluster of disease cases through reporting by a clinician or analysis of surveillance data may an investigation take place and any necessary control measures be implemented.

Frontline clinicians play a crucial role in recognizing patients with an unusual constellation of symptoms, symptoms of a disease of public health importance that is rarely seen in the United States, a severe presentation of what is typically a less severe infectious disease, or a severe illness with the hallmarks of infectious disease for which a diagnosis cannot be found. Such cases take on even more importance when the patient has a history of international travel, exposure to exotic animals, or other unusual exposures. When such cases are reported to public health, often they can be evaluated with diagnostic methods that may not be available commercially.

This chapter describes the mutually beneficial collaboration between public health and infectious disease clinicians.

PUBLIC HEALTH

“The success or failure of any government in the final analysis must be measured by the well-being of its citizens. Nothing can be more important to a state than its public health; the state’s paramount concern should be the health of its people.”

—Franklin Delano Roosevelt, 1932

The US Centers for Disease Control and Prevention (CDC) defines public health as the science of protecting and improving the health of families and communities through promotion of healthy lifestyles, research on disease and injury prevention, and detection and control of infectious diseases.²⁶ This chapter focuses on the prevention and control of infectious diseases, although the same principles can be applied to many other health problems.

INFECTIOUS DISEASE SURVEILLANCE

One of the essential services of public health is monitoring the health of the population. Public health surveillance is one method used to monitor the incidence of infectious diseases. The CDC Working Group on Public Health Surveillance Systems defines public health surveillance as “the ongoing, systematic collection, analysis, interpretation, and dissemination of data about a health-related event for use in public health action to reduce morbidity and mortality and to improve health” and notes that outbreak identification requires “an increase in frequency of disease above the background occurrence of the disease.”¹⁰

The Institute of Medicine’s 1988 report on the future of public health highlighted the role and goals of surveillance by recognizing that

one of the three core functions of public health—assessment—relies on public health surveillance to identify and describe problems, guide decisions about appropriate actions, and monitor progress.⁶⁸

In 2011, the US Council of State and Territorial Epidemiologists stated that the overarching goal of surveillance is “[t]o provide actionable health information to public health staff, government leaders, and the public to guide public health policy and programs.”⁹²

Uses of infectious disease surveillance data include identifying outbreaks, informing and evaluating disease prevention and control efforts, determining vaccination strategies and assessing vaccine safety and effectiveness, monitoring antimicrobial resistance, monitoring health care–associated infections, and guiding allocation of resources for disease prevention, control, and treatment programs.

In the United States, the CDC and state, local, and territorial health departments carry out public health functions, including infectious disease surveillance. Public health authorities at the CDC, state, and territorial health departments collaborate in determining which diseases should be nationally notifiable to the CDC. Additionally, reporting of specified infectious diseases is required by law in each state. Although health care providers and laboratories are typically designated reporters, state laws vary with regard to the persons who are responsible for reporting, the diseases or conditions that are reportable, and the circumstances under which reporting is to occur.⁶ Specific information is generally available online or on request from state or local public health agencies.

Although public health is responsible for evaluating and taking action on infectious diseases identified through disease surveillance, unless a report of disease is initiated by a health care provider, infection preventionist, or laboratory, no information is generated. Without baseline data on the incidence of infectious diseases, an increase or decrease in cases might not be recognized. Timely and accurate public health surveillance data can lead to earlier outbreak detection and more rapid implementation of prevention and control measures. In addition, the impact of intervention activities and other public health activities can be evaluated more accurately, leading to a more rational establishment of priorities and resource allocation.

However, the collection of data without analysis, interpretation, and dissemination of the data is of no value. Public health surveillance data obtained by both traditional and nontraditional means, such as syndromic surveillance, can be used for immediate public health action, program planning and evaluation, and formulating research hypotheses.^{13,12} When used properly, surveillance data help in directing disease prevention and control activities and evaluating their impact.

Incentives to primary reporting sources to maintain good reporting, such as ongoing feedback, are essential for maintaining a useful surveillance system. After surveillance data are analyzed, the results are relayed to the primary reporting source and to others interested in the data. Such feedback serves to sustain interest in the reporting system and thereby maintains the quality of data obtained and continuously updates persons at each level of the surveillance system about the changing patterns of disease occurrence and new strategies for disease prevention and control.

One vehicle for the feedback of national surveillance information is the *Morbidity and Mortality Weekly Report*, which is published by the CDC.³⁷ The CDC also publishes periodic summaries of surveillance activities relating to specific diseases. In addition, regular summaries of surveillance activities are published by many state and local health departments as well as the World Health Organization (WHO).¹⁰⁰ Today,

most public health agencies have publically accessible websites, and most of these summaries are easily available online.

Increased use of automated reporting systems using electronic health records and laboratory results has streamlined the reporting process and improved the completeness and timeliness of surveillance data.²⁰ In addition, social media is increasingly playing a role in infectious disease surveillance. Public health practitioners use social media to monitor trends, collect data, and provide information; the public uses social media to monitor and report diseases and obtain information. The use of social media and online resources will continue to enhance public health surveillance.

HOW PUBLIC HEALTH CAN ASSIST CLINICIANS

Clinicians can contact public health agencies for consultation when they encounter patients who may have infectious diseases with known, unknown, or unclear etiologies, or when an outbreak is suspected. When a clinician encounters a patient who has an unusual or severe presentation of what appears to be an infectious disease or becomes aware of a cluster of patients with similar symptoms, public health may be able to assist with determining a diagnosis. Public health also investigates suspected outbreaks of infectious disease and implements outbreak control measures.

Point-of-care bidirectional communication between public health practitioners and clinicians can facilitate clinical decision making based on the most current public health information. For example, public health practitioners can inform clinicians about infectious diseases known to be circulating in the area of the patient's residence and about infectious diseases patients may have been exposed to during travel. Public health practitioners can also provide recommendations for treatment and isolation of infected patients and postexposure prophylaxis for their contacts, including first responders such as emergency medical services personnel.

In addition, public health laboratories can be extremely helpful to clinicians. Although clinical laboratories provide excellent service for routine testing, they may not be able to test for more obscure pathogens. If an unusual disease is suspected, public health laboratories can perform testing for an array of possible agents, including biologic threats. Public health practitioners and laboratories also may be able to assist clinicians in establishing a diagnosis when the differential diagnosis contains several possible infectious disease entities with similar clinical presentations. New infectious disease diagnostic technologies will continue to be developed and are likely to be initially available only at public health laboratories.

Public health laboratories can often also detect more common pathogens such as *Neisseria meningitidis* or *Streptococcus pneumoniae* in clinical specimens that have not grown in culture in clinical laboratories by using nucleic acid–based assays such as polymerase chain reaction (PCR) because the sensitivity of the PCR test is not affected by prior antibiotic treatment.⁸³ Public health laboratories may also perform PCR testing for other diseases such as measles, which can be diagnostically challenging in an era of low incidence.

In addition to identifying disease-causing pathogens, public health laboratories are able to use molecular methods to perform strain typing that further characterizes pathogens and may identify novel strain types. Such testing may also detect new agents and identify outbreaks. A public health laboratory first identified 2009 pandemic H1N1 influenza A, which at the time was a novel influenza strain.

Advancement in laboratory methods has also enhanced the usefulness of surveillance data in outbreak detection by linking bacterial isolates obtained from geographically scattered cases. CDC coordinates PulseNet,³⁹ a national network of public health and food regulatory agency laboratories that connects foodborne illness cases to detect outbreaks. PulseNet uses a variety of methods to subtype *Escherichia coli* (O157 and other Shiga toxin–producing *E. coli*), *Campylobacter*, *Listeria monocytogenes*, *Salmonella*, *Shigella*, *Vibrio cholerae*, *Vibrio parahaemolyticus*, and *Cronobacter* isolates. Pulsed-field gel electrophoresis (PFGE), multiple-locus variable-number tandem repeat analysis (MLVA), and whole-genome sequencing (WGS) are PulseNet's main subtyping (or "fingerprinting") tools. These molecular fingerprints, or patterns, are submitted electronically to a dynamic database at CDC. This database

is available on demand to participants, which allows for rapid comparison of the patterns and identification of clusters of cases, which can lead to identification and removal of contaminated food products from the homes of consumers thereby preventing further disease. In addition to foodborne outbreaks, PulseNet has also identified outbreaks caused by bacteria from animal and water sources.

The use of culture-independent diagnostic tests (CIDTs) is rapidly changing the way that clinical laboratories diagnose patients with infectious diseases. Antigen-based tests and nucleic acid–based assays that do not depend on culture and produce no isolate have become increasingly common. Almost all *Clostridium difficile*, *Legionella* spp., *Bordetella pertussis* and influenza cases are now diagnosed by CIDTs.⁷³ The use of CIDTs for enteric infections such as *Campylobacter* and Shiga toxin–producing *E. coli* is also very common.⁶⁶ The use of CIDTs has implications for public health surveillance because bacterial isolates are needed for molecular characterization, which may be used in addition to other data to attribute illness to specific sources. In addition, isolates are necessary for antimicrobial resistance testing. Although PCR testing is available for many of the known genes that cause antimicrobial resistance, new resistance genes would not be detected. Therefore, public health laboratories will continue to request some CIDT-positive specimens from clinical laboratories for culture and isolate-based monitoring until new testing methods, such as metagenomics and next-generation sequencing technology that work directly on clinical specimens, become established.^{39,47}

Another CDC online tool is MicrobeNet, which can be used by clinicians, hospitals, and public health to rapidly identify rare and emerging infections. Traditionally, clinicians or laboratorians who needed to identify rare bacteria or fungi or to confirm an infectious disease diagnosis due to an uncommon organism needed to send a sample to the CDC and await test results. MicrobeNet provides access to the CDC's virtual microbe library of more than 2400 rare and emerging infectious bacteria and fungi and helps public health laboratories and hospitals quickly identify some of the most difficult pathogens to grow and detect.³⁶

OUTBREAK INVESTIGATION

When faced with an unusual case or cluster of cases that may be of public health concern, public health authorities conduct an investigation in an attempt to determine or confirm a diagnosis, describe the scope of the problem, and, if unknown, identify a cause. Front-line clinicians may be called on to assist in such investigations.

When investigating a possible outbreak, a useful approach is for investigators to address the inquiry systematically using the CDC's 10-step method⁴¹:

Prepare for Fieldwork

The following are the steps in preparing for fieldwork:

1. Establish the existence of an outbreak
2. Verify the diagnosis
3. Define and identify cases
4. Describe and orient the data in terms of time, place, and person
5. Develop hypotheses
6. Evaluate hypotheses
7. Refine hypotheses and carry out additional studies
8. Implement control and prevention measures
9. Communicate findings

Several exercises illustrating these principles, including communicable and noncommunicable disease outbreaks, can be found at the CDC's training site for epidemic intelligence service officers.²⁸

PUBLIC HEALTH PREVENTION AND CONTROL MEASURES

After an unusual case or cluster of cases is recognized and an investigation has occurred, many tools are available for public health intervention, if it is indicated. Two important interventions, immunization and the treatment of individual patients, are not considered in this chapter because they are addressed at length elsewhere in this book.

Other public health tools that are not discussed here but are also relevant to the prevention and control of infectious diseases include modifications to human behaviors that affect exposure to infectious diseases such as sexual behavior and injection drug use, water and food sanitation, food preparation methods, burial practices, and so on.

Additionally, various prevention and control measures can be applied to animals, such as vaccination and treatment or prophylaxis, that decrease their risk for spreading diseases to humans.⁷¹ Finally, prevention and control measures can be applied to the environment, such as proper disposal of waste, vector control, and appropriate design and proper maintenance of buildings and other equipment that can reduce opportunities for disease transmission. An example of such a control measure would include proper maintenance of spas or cooling towers to prevent *Legionella* transmission.²⁴

Isolation

Isolation is the separation of persons who have a specific infectious illness from those who are healthy, and the restriction of their movement to stop the spread of that illness during the period of communicability.⁴⁰ Indications for isolation of patients with infectious diseases have changed greatly in the twentieth century with increasing knowledge about modes of transmission and with antimicrobial therapy, which rapidly renders patients with many diseases noninfectious. The American Academy of Pediatrics (AAP) *Red Book: Report of the Committee on Infectious Diseases* is an excellent resource for information about isolation recommendations.²

Quarantine

In addition to containing the spread of communicable illnesses through isolation, another less commonly used control measure is quarantine. Quarantine is the separation and restriction of movement of susceptible persons who, although not yet ill, have been exposed to an infectious agent and therefore may become infectious.³⁰ When quarantine is used it is imposed for a period equal to the longest usual incubation period of the disease.

The history and practice of quarantine began as early as the 14th century in Italy to control plague by requiring ships arriving in Venice from infected ports to anchor for 40 days before landing.³³ The Italian word, *quaranta*, meaning 40, evolved into the commonly used word *quarantine*.

In recent years, health departments in the United States have rarely implemented quarantine. However, it was used during the 2003 severe acute respiratory syndrome (SARS) outbreak, and it may also be used for susceptible persons who have been exposed to measles and did not receive timely postexposure prophylaxis.

Preexposure and Postexposure Prophylaxis

The word prophylaxis is used in this section to describe the use of antimicrobial or immunologic agents to prevent infection before or after exposure to an infectious disease. The decision to initiate preexposure or postexposure prophylaxis and the choice and dosage of agents require careful consideration of both the child's clinical status and the epidemiologic factors that may place the child at risk for acquiring the disease. Public health authorities should be notified of cases and exposures of reportable infectious diseases. A public health investigation may be conducted to ensure that all exposed persons have been identified and, when necessary, treated or placed under observation or even quarantine. In addition, public health practitioners can often provide useful additional information on recommended prophylaxis regimens. For detailed information on the use of prophylaxis to prevent specific infectious diseases, the regularly updated AAP *Red Book: Report of the Committee on Infectious Diseases* should be consulted.² In addition, the US Advisory Committee for Immunization Practices recommendations also contain information about prophylaxis for vaccine-preventable diseases.²⁵

COMMON PATTERNS OF DISEASE SPREAD

Animal-to-Person Spread

Many infectious diseases are transmitted from animals to humans (zoonoses). Of all emerging diseases in the 20th and 21st centuries, more than 75% are zoonotic in origin.⁵⁶ Clinicians who routinely inquire

about animal contacts as part of the clinical and epidemiologic history of an ill patient frequently find valuable clues to an obscure diagnosis.

Details of the clinical manifestations, differential diagnosis, and treatment of zoonoses are found in the appropriate chapters elsewhere in this book. For a complete description of the circumstances under which each agent is spread from animal to person, consult a textbook of zoonoses. Often, emerging and reemerging infectious diseases in humans, such as SARS, Middle East respiratory syndrome (MERS), and Ebola virus, are found to have an animal reservoir.^{1,59}

Person-to-Person Spread

As members of groups—including their families, schools, camps, child care centers, and religious organizations—children are at risk for acquiring or spreading infectious agents that are transmitted from person to person. Knowledge of the typical patterns of spread can be useful in planning surveillance or in designing prevention and control measures. For example, recognition that diarrheal illnesses can result from person-to-person spread in child care centers and that it can indicate inadequate hygienic practices may justify specific surveillance for diarrhea in that setting.

In this section, disease transmission in the household, child care centers, and schools is briefly discussed. The important areas of disease transmission in child care centers and hospitals are discussed in separate chapters in more depth. Maternal transmission of specific infections to the fetus or neonate is also reviewed elsewhere in this book.

EXAMPLES OF EXPOSURE SOURCES

Contaminated Food

Many foods have been shown to be the vehicle of transmission in outbreaks caused by a wide range of bacteria, viruses, and parasites, in addition to many naturally occurring toxins and human-made chemicals. Inherent contamination of meat, poultry, and eggs with *Salmonella*, Shiga toxin—producing *E. coli*, *Listeria*, and other pathogens, as well as deficiencies in food storage and preparation and ingestion of raw or improperly cooked animal products in both eating establishments and the home, still contribute to outbreaks and sporadic cases of gastrointestinal infectious diseases.^{48,60,61,64} In addition, practices with known risks such as drinking unpasteurized milk can result in infection.³¹

Outbreaks of infection and secondary hemolytic uremic syndrome resulting from infection with Shiga toxin—producing *E. coli* strains such as O157:H7 and O104:H4 have been related to juice,⁹⁷ ground beef,⁸⁷ spinach,¹⁴ sprouts,⁹ unpasteurized milk,^{51,57} and other food items. In addition, new problems can result from changes in the food industry and in patterns of food consumption.⁵⁰ In recent years, several large outbreaks of salmonellosis have been associated with the widespread distribution of fresh produce, a previously rare vehicle of *Salmonella* transmission.⁵

The CDC publishes the Foodborne Outbreak Online Database,³² and although the number of outbreaks reported to public health authorities represents only a small fraction of those that occur, these reports can provide important insight into the epidemiology of foodborne disease.

Clinicians must work in conjunction with public health authorities by confirming diagnoses through appropriate diagnostic methods and promptly reporting findings or suspicions of foodborne illness so that foodborne outbreaks can be recognized in a timely fashion to control and prevent these illnesses most effectively.

Recreational Water

Water can be a source of infectious disease, and outbreaks of waterborne disease associated with recreational water use, such as swimming or wading^{46,63,86}; use of hot tubs, spas, and water parks^{16,67,72}; and exposure to decorative fountains⁹³ have been reported. Diseases transmitted in this manner include shigellosis, cryptosporidiosis, norovirus gastroenteritis, viral conjunctivitis, giardiasis, legionellosis, enterohemorrhagic *E. coli* O157:H7, and *Pseudomonas* dermatitis ("hot tub folliculitis").⁹⁰

Deaths may occur, especially with cases of primary amebic meningoencephalitis caused by any of several free-living amebae in persons

who had recently been swimming, typically in warm, stagnant water.^{7,78} In the United States, these infections have traditionally been reported in southern-tier states, with more than half of infections occurring in Texas and Florida.³⁸ However, in 2010 and 2012, *Naegleria fowleri* infections were documented in Minnesota, an area at much higher latitude than previous US cases.⁶⁹

Unpasteurized Milk

Unpasteurized or “raw” milk has been demonstrated as the vehicle of transmission in outbreaks of brucellosis, tuberculosis, and diphtheria, as well as outbreaks of diseases caused by group A streptococci, *Salmonella*, *Shigella*, *Campylobacter*, *Listeria*, *Yersinia enterocolitica*, and staphylococcal toxin.^{49,75} Exposure to unpasteurized milk should be rare in the United States. Unfortunately, the use of raw milk as a “health food” continues to account for outbreaks of disease, particularly outbreaks caused by *E. coli* O157:H7, *Salmonella*, and *Campylobacter*.^{31,57,75,84} In addition, children sometimes drink raw milk while visiting dairy farms on school field trips, during other youth activities, or during travel to other countries, which puts them at risk for infectious diarrhea and Shiga toxin-producing *E. coli*-related renal failure.

VECTORBORNE DISEASE

Vectors such as mosquitoes and ticks can transmit infectious diseases. Examples of tick-borne diseases in the United States include anaplasmosis, babesiosis, ehrlichiosis, Lyme disease, Rocky Mountain spotted fever, tick-borne relapsing fever, tick paralysis, and tularemia.^{23,52} Mosquito-borne diseases that have been found in the United States include West Nile virus infection, eastern equine encephalitis, La Crosse encephalitis, St. Louis encephalitis, and western equine encephalitis.⁴² Outbreaks of locally transmitted cases of malaria in the United States have been small and relatively isolated,³⁵ but several dengue outbreaks have been detected in the United States since 1980, including seven outbreaks in southern Texas along the United States–Mexico border, one outbreak in Hawaii in 2001, and two outbreaks in southern Florida in 2009 and 2010.⁹⁴ Other vectorborne infections that can be carried back from foreign travel include Zika virus, chikungunya, dengue, Rift Valley fever, yellow fever, and many others. In addition, fleas can spread endemic or murine typhus, plague, and cat-scratch fever, and body lice can spread epidemic typhus, relapsing fever, and trench fever.

The CDC has excellent online resources for vectorborne diseases,²⁷ and local and state public health practitioners can provide clinicians with information on vectorborne diseases in the geographic regions they serve and other regions where patients may have traveled. In addition, public health laboratories may be able to assist in establishing a diagnosis.

Personal protection against vectors such as mosquitoes and ticks includes avoiding vector-infested areas and having an awareness of peak exposure times and places, wearing protective clothing, using insect repellents applied to skin or clothing and spatial repellents, using bed nets, and frequently inspecting for and promptly removing attached ticks.⁸² These individual preventive measures can be practiced in any circumstance where exposure to infected mosquitoes or ticks may occur.

Bioterrorism and Natural Disasters

Unfortunately, an important responsibility of public health authorities is to help prepare the nation and clinicians for the possibility of biologic, radiologic, or chemical terrorism and natural disasters. Children have special vulnerabilities to biologic terrorism and chemical agents because of their unique physiology and the limited availability of age-appropriate and weight-appropriate antidotes and treatments.^{58,81} Also, clinicians’ unfamiliarity with presenting clinical syndromes from either biologic or chemical exposures could delay appropriate diagnosis and treatment.^{45,58,89}

Another issue is that the Strategic National Stockpile, a national repository of antimicrobial agents, chemical antidotes, antitoxins, and other life-support medications and equipment, can only stockpile US Food and Drug Administration (FDA)-licensed items and only for their FDA-approved indications.⁹⁵ Often FDA indications for antimicrobial and other therapeutic agents for children after a biologic agent release

are lacking, causing the stockpile to be deficient in certain therapeutic agents for children.

Terrorism preparedness is a unique and hopefully rare component of general emergency and disaster preparedness. However, natural disasters are more common, and infections that are typically rare in the United States can result from compromised personal hygiene, wounds and injuries, contaminated food and water, and exposure to insect vectors. Prompt recognition and appropriate management by clinicians of unusual diseases are critical during and after disaster situations.

COMMON DISEASE TRANSMISSION SETTINGS

Households

Spread of disease in households is common, and transmission can be considered in two stages: introduction of the agent into the family, usually by a single member, and spread to other family members.⁸ Spread to other members can be described in terms of rapidity and intensity, the latter commonly measured by the secondary infection rate (or secondary attack rate), which is defined as the proportion of the contacts of the index carrier or index case who become infected (or ill) in a given interval after exposure. The secondary infection rate varies from agent to agent and may be affected by the age, sex, and infectivity of the introducer; the size of the family; crowding; the age of household contacts; previous immunity; and interventions attempted, including vaccination, isolation, treatment, and prophylaxis. The ratio of the secondary attack rate to the incidence of disease in the community is a measure of the importance of the family as a focus of disease.^{55,77}

Child Care Centers

It is well known that infectious disease agents are easily transmitted among children in child care centers and that outbreaks occur in these settings.^{22,74,101} (see Chapter 248). Interventions that have proved valuable for reducing infections within child care centers include formal written policies for infection prevention and control within the child care center, formal education of child care center staff concerning infection prevention practices, good hand hygiene by both staff and children, appropriate cleaning of contaminated surfaces and items, separation of food preparation and diaper changing areas, exclusion of certain ill children, cohorting ill children when exclusion is not possible, and ensuring adequate age-appropriate immunization of child care attendees and staff and optimal ratios of children to staff.^{62,98}

Schools

Typically, infectious disease spread in schools is less than that in families and child care centers. However, schools may serve to spread infection from family to family. Settings that result in a greater level of person-to-person contact than is found in typical classroom settings, such as participation in school sports¹⁷ or attendance at boarding schools, summer camps, and college dormitories, also can result in more efficient transmission of disease.^{3,65,88,91} In recent years, measles, mumps, influenza, meningococcal disease, norovirus, and methicillin-resistant *Staphylococcus aureus* outbreaks have occurred in these settings.^{17,19,15,18,76,96}

HEALTH INFORMATION FOR INTERNATIONAL TRAVEL

International travel, whether by child or adult, necessitates preparation beforehand to obtain the proper immunizations and contingency plans for the possibility of encountering unsanitary food or water during the travel.^{43,53,70,80} Illnesses acquired abroad may not be manifested until after returning home, with consequent diagnostic difficulty. Clinicians should query parents regarding travel when children have unusual symptoms or acute febrile rash illnesses.

Active and passive immunization are covered elsewhere in this book, and updated travel-related immunization information is available at the CDC’s traveler’s health website.^{42,43,80} Disease-specific information for travelers and clinicians is available in the CDC’s “Yellow Book” at that website,⁴² including information on international travel with infants and children.⁹⁹ In addition, travel notices are available that can alert travelers and clinicians to infectious disease outbreaks occurring

throughout the world. It should also be noted that measles remains endemic in much of the world outside of the Western Hemisphere, including some European countries. Infants traveling to parts of the world where measles is circulating should be vaccinated as young as 6 months of age.²¹

Safe water may be found in many hotels in large cities throughout the world, but only water from adequately chlorinated sources can be considered truly safe. Where chlorinated water is not available, canned or bottled carbonated beverages and beverages made from boiled water or that contain alcohol may be safe; however, an outbreak caused by commercially bottled water contaminated by non-O1 *Vibrio cholerae* has been described.¹¹ Ice made from untreated water may contaminate an otherwise safe beverage, either directly or by leaving contaminated water on the outside of the container. The CDC has prepared guidance on preparation and storage of safe water that can be found online.²⁹

Food should also be selected carefully. In areas of the world where hygiene and sanitation are poor, travelers should avoid salads, uncooked vegetables, unpasteurized milk, and milk products such as cheese and should eat only fruits and vegetables that can be peeled by the traveler or have been cooked and are still hot. In addition to the recommendation that all children receive hepatitis A vaccine, persons who are traveling to countries with high or intermediate levels of endemic hepatitis A infection are recommended to receive hepatitis A vaccine before departure.⁵⁴

Children younger than 2 years of age have a high risk for acquiring traveler's diarrhea.^{4,79,85} Traveler's diarrhea is caused by several bacterial pathogens, including *E. coli*, *Shigella*, *Campylobacter*, *Salmonella*, *Aeromonas*, *Plesiomonas*, and noncholera vibrios. Noroviruses are also an important cause of morbidity among travelers, and outbreaks on cruise ships are frequently reported.³⁴ Some travelers may be at increased risk because genetic risk factors associated with susceptibility to specific pathogens have been identified.⁴

Immediate medical attention should be sought for an infant or child with blood or mucus in the stool, fever with rigors, or persistent vomiting or diarrhea with dehydration. Because infants and small children are particularly at risk for becoming dehydrated, parents need to be aware of the signs of dehydration and be prepared to use oral rehydration solutions containing appropriate concentrations or electrolytes as a preventive measure while medical attention is being obtained. WHO oral rehydration solutions are widely available at stores and pharmacies in most developing countries.

For more information on traveler's diarrhea, including antimicrobial treatment and oral rehydration therapy, please see the CDC Yellow Book.⁴²

For travel to areas where vectorborne diseases circulate, guidance on general protective measures for mosquitoes, ticks, and other arthropods, including the use of insect repellents for children, can be found in the CDC Yellow Book.⁸²

SUMMARY

By working together to leverage the strengths and resources of both, clinicians and public health practitioners are partners in protecting and improving the health of the community.

When parents are employed outside of the home or are otherwise unable to care for their preschool children during all or part of the day, they make arrangements for child care during their time away. The term child care encompasses a large variety of options in the absence of a parent or legal guardian. These include (1) small family child care homes that provide care for six or fewer children, usually in the home of the care provider; (2) large family child care homes that provide care for seven to 12 children, usually in the home of the care provider; (3) large child care centers housed in nonresidential settings that provide care for at least seven children in one location; and (4) facilities that care for ill children who are temporarily unable to attend their regular child care setting for health reasons.¹⁵

Of the estimated 20 million children younger than 5 years identified in the 2010 US Census, approximately 12 million (60%) attended some type of regular child care arrangement at least once a week. Approximately half of these received care provided by parents or relatives. Nearly 4.5 million (23%) preschool-aged children were cared for in an out-of-home organized child care facility (such as a child care center, nursery, or preschool), and 2.4 million (12%) had care provided by a nonrelative either in their own home or a family child care setting.¹⁸³ Federal statistics on the health and well-being of children indicate that in 2012, approximately 61% of children in the United States, aged 3 to 6 years, who were not yet attending kindergarten were enrolled in center-based child care—that is, child care centers, prekindergarten, nursery school, Head Start programs, and other early childhood education programs.¹⁰⁵

The child care center for preschool-aged children is an optimal setting for infectious agents to be readily transmitted among children and staff. Therefore policies and practices that attend to the control and prevention of infectious disease are a major component of child care licensing procedures.^{15,16} All states in the United States have licensing regulations for out-of-home child care. However, they are primarily directed toward child care centers, thus missing the majority of children attending child care homes.

FACTORS AFFECTING TRANSMISSION OF INFECTIOUS AGENTS

Numerous studies have demonstrated increased numbers of infections in children attending out-of-home group child care compared with those cared for at home.^{27,76,87,99,100,153,208–210,284} The first year of child care attendance has been identified as a period of increased incidence of infectious illness among child care attendees in several studies. However, after this time period, incidence decreases, and results suggest that earlier child care attendance is protective of respiratory^{27,87,154} or gastrointestinal^{99,100,153} illness before school entry.

Multiple factors can contribute to the transmission of infectious agents in the group child care setting (Box 248.1), the most important of which are host factors relating to the immunologic susceptibility of young children. Children younger than 5 years do not naturally have fully developed immunity against the polysaccharide antigens of respiratory pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*, and *Kingella kingae*.²⁸⁷ The natural tendency for intimacy in an age group that has not established acceptable toileting practices and is not knowledgeable or fully capable of basic hygienic practices increases the chances of transmission from an infected child to another or to staff. In larger child care centers, children are usually placed in age cohorts, and thus the immunologically less mature are more contagious to each other and have greater tendency to develop illness. Respiratory and gastrointestinal pathogens frequently contaminate toys and environmental surfaces. Infants and toddlers are indiscriminate

in mouthing objects and fingers, thus contributing to the potential organisms that naturally populate the saliva and the respiratory tract to be transmitted readily from child to child.

Unique risk factors identified as particularly important in the spread of gastrointestinal organisms are large numbers of diaper-aged children in centers where staff members who diaper children are also responsible for food preparation.^{30,131} Separating diaper-aged children from those who are older is important to limit spread of enteric illness. If meals are prepared in the child care setting, separating this activity from toilet areas is essential. Current national guidelines recommend separate staff for handling food and diapering children in facilities large enough to have adequate staffing.^{14,19} In addition, overcrowding, understaffing, and poorly designed physical environments can foster transmission of infectious agents in child care facilities. A lack of or inadequate number of hand-washing facilities or hand-sanitizing solutions for children and providers creates an almost insurmountable barrier to infection control. Other risk factors are related to the age of the participants, the number of children, and the ratio of staff to children. The last is determined in part by the age of the children; younger children require higher staff-to-child ratios. In overcrowded situations with inadequate staff, infection can be spread easily because of inappropriate hand hygiene or inattention to other facets of infection control. Parental situations may also factor into increased risk because parents may choose not to withdraw ill children from attendance at child care because of the expense and inconvenience of creating alternate child care arrangements, thus further exposing other children and staff to infectious agents. Availability and accessibility of resources for care of ill children in these situations would also reduce the risk for further spread of illness.

MODES OF TRANSMISSION OF INFECTIOUS DISEASES IN OUT-OF-HOME CHILD CARE

The major modes of transmission of infectious agents in out-of-home child care are respiratory, gastrointestinal (primarily fecal-oral), direct person-to-person contact, indirect contact with contaminated fomites, and contact with infected body fluids—blood, urine, or saliva. Some infections may be transmitted in more than one way (e.g., herpes simplex virus [HSV] can be spread through direct contact with broken skin or mucosal exposure to infected body fluids). The most important pathogens and their modes of transmission of infection in out-of-home child care are shown in Table 248.1. Respiratory and gastrointestinal infections are the most common causes of illness in infants, toddlers, and preschoolers, regardless of whether these children attend out-of-home child care.¹⁵⁵

Respiratory

For some microbiologic species causing infection, the mode of transmission is the airborne route. Direct contact with the infected individual is not necessary for the spread of the infection. When an infected person coughs, sneezes, or sings, the organism is aerosolized into small droplets (<5 µm) and can remain suspended in the air for several hours. These aerosol nuclei are capable of traveling distances on air currents. Agents known to be transmitted by this means include the measles and varicella viruses and *Mycobacterium tuberculosis*.

Most commonly, respiratory organisms are spread by the production of droplets laden with infective particles. When an infected person talks, sneezes, or coughs, droplets containing these microorganisms are formed, expelled, and may land on the mucosa of another individual. These droplets may also be transmitted directly from mucosa to mucosa when close physical contact occurs. More often, droplets land on nonporous surfaces (e.g., cribs, tables, toys, chairs) or on clothes and paper (fomites)

and remain infective for minutes to hours. Hand contact with contaminated surfaces and fomites can result in infection if the hands touch the nasal or conjunctival mucosa.^{134,155} Agents that can be transmitted by droplet spread from mucosa to mucosa, from finger to mucosa, or by fomites include most respiratory viruses (respiratory syncytial virus [RSV],

rhinovirus, human metapneumovirus, coronavirus, human herpesvirus type 6 [HHV-6], influenza virus, parainfluenza virus, adenovirus, parvovirus B19, measles virus, mumps virus, rubella virus, and varicella zoster virus), *Bordetella pertussis*, *Haemophilus influenzae* type b (HIB), *S. pneumoniae*, *N. meningitidis*, and *Streptococcus pyogenes*.^{101,114,115,130,133,134} Finger-to-mucosa spread of respiratory pathogens is the most important and common mechanism for transmission of viral and bacterial infections and is a mechanism of self-inoculation.¹⁴³ Consequently, hand hygiene that includes hand washing and the use of alcohol-based sanitizers is an essential element of preventing spread of infection.^{155,237}

BOX 248.1 Risk Factors for Infectious Disease in Child Care Facilities

Children

Immunologic susceptibility to infectious agents
Lack of or poor hygiene around toileting
Natural tendency to intimacy
Frequent oral contact with objects in the environment
Lack of awareness and practice of good hygiene

Caregivers

Insufficient training in infection control
Lack of policy regarding immunization
Inadequate screening for infectious diseases

Environmental Issues

Inappropriate staff-to-child ratios
Overcrowding
Failure to separate age groups
Poorly designed physical layout

- Inadequate or poorly placed sinks
- Toilet areas and food preparation areas and personnel are not separate

Parents

Pressure to admit sick children to out-of-home child care

Gastrointestinal

Gastrointestinal pathogens are most commonly spread by the fecal-oral route. The number of organisms required to produce infection will determine whether infection occurs by person-to-person spread or whether a food or fluid intermediary is required. Organisms such as rotavirus, *Giardia lamblia*, and *Shigella* spp. require very low inoculum to transmit infection and can be carried on the hands (without obvious gross contamination) after person-to-person contact or by the touching of infected surfaces. In contrast, *Salmonella*, rarely a cause of diarrheal outbreaks in the child care setting, requires large numbers of organisms to produce infection. For these pathogens, an intermediary step of food or beverage contamination is required to allow organisms to replicate up to the necessary inocula.

Numerous studies have demonstrated fecal organisms on child care center environmental surfaces with which infants and toddlers have had contact, as well as on the hands of care providers.^{98,168,280,289} Contamination of the environment is highest when the child care attendees are younger than 3 years. This age predilection correlates with the number of children still wearing diapers.^{266,281} Several important pathogens, including fecal bacteria, rotavirus, hepatitis A virus (HAV), and *G. lamblia* cysts, are able to survive on environmental surfaces for periods ranging from hours to weeks,^{71,179} therefore increasing opportunities for transmission in the absence of effective environmental cleaning standards.

TABLE 248.1 Pathogens and Modes of Transmission of Infection in Day Care

Mode of Transmission	Bacteria	Viruses	Parasites
Respiratory	<i>Haemophilus influenzae</i> type b <i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> Group A <i>Streptococcus</i> <i>Bordetella pertussis</i> <i>Mycobacterium tuberculosis</i> <i>Kingella kingae</i>	Adenovirus Coronavirus Human metapneumovirus Influenza A and B Measles Mumps Parainfluenza Parvovirus B19 Respiratory syncytial Rhinovirus Rubella Varicella zoster	
Fecal-oral	<i>Campylobacter</i> spp. <i>Clostridium difficile</i> Shiga toxin-producing <i>Escherichia coli</i> (e.g., O157:H7) <i>Salmonella</i> spp. <i>Shigella</i> spp.	Enteroviruses Hepatitis A Enteric adenovirus Astrovirus Calicivirus (norovirus and sapovirus) Enterovirus Rotavirus Astrovirus	<i>Cryptosporidium parvum</i> <i>Enterobius vermicularis</i> <i>Giardia lamblia</i>
Person-to-person by skin contact	Group A <i>Streptococcus</i> <i>Staphylococcus aureus</i>	Herpes simplex Varicella zoster (shingles)	<i>Pediculus capitis</i> <i>Sarcoptes scabiei</i> <i>Trichophyton</i> spp. <i>Microsporum</i> spp.
Contact with urine or saliva		Cytomegalovirus Herpes simplex virus	
Contact with blood		Hepatitis B virus Hepatitis C virus Cytomegalovirus Human immunodeficiency virus	

Skin to Skin

Bacterial, viral, and parasitic infections of the skin can be transmitted person to person by direct contact. Bacterial pathogens such as *S. pyogenes* and *Staphylococcus aureus* usually are not invasive unless a break in the integument occurs, such as after minor trauma (e.g., insect bites). HSV may be transmitted from skin or mucosa to skin by direct contact, again only if the skin is broken. Infestations such as scabies and lice are transmitted person to person by mobile parasites. The superficial dermatophytes responsible for tinea infections (*Trichophyton*, *Microsporum*, and *Epidermophyton*) are transmitted by person-to-person spread or by contact with infected fomites such as combs, hairbrushes, and hats.

Blood, Urine, and Saliva

Hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV) are blood-borne pathogens with rare potential to be transmitted in the child care setting. Although both hepatitis B and HIV can be demonstrated at very low levels in urine and saliva, exchange of these body fluids is very unlikely to transmit infection. Enzymes present in saliva can inactivate the HIV virus. Risk for transmission of HIV through saliva increases if there is visible blood present in saliva (which may occur if the biter has bleeding gums or periodontal disease).

Bites in child care are always of concern because this is a behavioral manifestation primarily exhibited by preschoolers. The highest risk for transmission of a blood-borne pathogen by a bite would be to the biter if blood is drawn or already present (e.g., severe dermatitis) or to the person bitten if infected blood is present in saliva.²⁹ Reports of HBV transmission through biting are rare and occurred before the vaccine era²⁰¹. To date, there have been no reports of transmission of HIV through biting in a child-care setting.⁴³

At child care centers, transmission of cytomegalovirus (CMV) or HSV most commonly occurs among attendees by contamination of toys with saliva. CMV is primarily shed in urine and saliva, although it is present in blood and seminal fluid. Asymptomatic infants and toddlers can shed virus in urine and saliva for months.^{3,45,93} Early studies demonstrated contaminated fomites and environmental surfaces as potential sources of transmission.^{102,216} Care providers and family members can become infected with CMV by the finger-to-mucosa route after contamination of hands by urine or saliva.⁴⁶ This is of concern because the greatest consequence of CMV infection is primary infection of a pregnant care provider leading to symptomatic congenital infection with CMV.

PREVENTION AND CONTROL OF INFECTIONS IN OUT-OF-HOME CHILD CARE

The American Academy of Pediatrics (AAP), the American Public Health Association, and the National Resource Center for Health and Safety in Child Care and Early Education have developed consensus guidelines on planning and practices in child care that promote the health and safety of children in out-of-home child care, including practices that prevent and control the spread of infection. This includes information on collecting, reviewing, and maintaining health records of children and staff, planning the physical space of the facility, methods of cleaning and disinfecting spaces, educating staff and families on recognizing potentially infectious illnesses, and establishing exclusion policies for specific infections.^{14,16,19}

Written Policies

Each child care facility should have written policies for preventing and managing child and staff illness due to transmissible agents. Policies should define roles and responsibilities of child care staff in preventing infectious illnesses. Written documentation should include policies for hand hygiene and personal hygiene procedures, environmental cleaning procedures; collecting, filing, and updating health and immunization records on all children and staff; education of child care personnel about health issues; communicating with parents; determining when a child or staff member should be excluded from the facility because of infection and when they can return; and working with public health officials in reporting and managing any outbreaks. Policies should also define the use of Standard Precautions and procedures to minimize

risk to potentially infectious blood and body fluids. Large child care centers benefit from having a health professional consultant for their health and safety procedures.¹⁴

Hand Hygiene

The key factor in prevention of disease in the child care setting is maintenance of optimal hygienic standards based on recognized mechanisms of transmission of infection. Hand hygiene is considered the single most important preventive measure.^{38,125,176,223,237} Hands are in constant motion and readily spread respiratory and enteric pathogens around the environment. Adequate hand hygiene includes hand washing with soap and water for 20 seconds and the use of alcohol-based sanitizers.

Two randomized intervention studies showed a modest benefit of increased attention to hand washing in preventing respiratory infections in children younger than 2 years and in preventing episodes of diarrhea in children older than 2 years.^{229,230} Two other studies have evaluated the role of alcohol-based sanitizers in the homes of children in out-of-home child care in reducing the secondary spread of illness. One demonstrated a reduction in gastrointestinal illness among family members²³⁷ and the other a reduction in respiratory illnesses.¹⁸⁴ Applicability to the child care environment also has been evaluated as part of several multipronged interventional programs.¹⁵⁵ A meta-analysis of studies evaluating the effect of hand hygiene interventions on reducing respiratory and gastrointestinal illness in community settings showed interventions that involved hand hygiene education plus the use of ordinary soaps had the greatest decrease in gastrointestinal and respiratory illnesses. The majority of studies evaluated were performed in child care centers and involved children younger than 5 years. No significant differences in benefits were noted with the use of alcohol-based sanitizers or antibacterial soaps compared with hand washing with nonantibacterial soap.⁸

Environment and Physical Plant Standards

In the planning of child care facilities, space and equipment needs that minimize the risk for transmission of infectious agents must be considered. Because fecal contamination is related strongly and inversely to age, having physical premises large enough to separate diapered children from older children is important. Food handling and storage areas should be separated from the toileting and diapering space. When tables in the play area are used for food, they must be sanitized before food service. Because contamination of hands is the most critical factor in transmission of infection, hand-washing facilities must be easily available to staff and children. Such facilities are especially important in the diaper-changing, toileting, and food preparation areas, and separate sinks should be used in each of these areas. The hand-washing sinks should be made of nonporous materials and preferably be hands-free and in easy reach of soap and towel dispensers.

Because feces-contaminated surfaces are major vehicles for the spread of enteric infections, particular care must be taken in planning the space and selecting equipment for diaper changing and toileting activities. The choice of equipment should be based on durability and ease of cleaning and disinfecting. Sinks, supplies, and waste containers should be placed within easy reach of the diapering table. The toddler area should be equipped with training toilets and junior-sized toilets with appropriate steps. The use of potty chairs is strongly discouraged.¹⁵

Kotch and colleagues performed a randomized intervention trial comparing frequency of diarrheal illnesses and related absences in 23 matched child care centers in North Carolina.¹⁷⁵ All received education on hygienic practices, but the intervention centers also had equipment installed for diapering, food handling, and hand washing that was designed to reduce transmission of pathogens (e.g., hands-free operations, nonporous surfaces). The intervention group showed a decrease in frequency of diarrheal illness (0.9 vs. 1.58 illnesses per 100 child-days). Caregivers in the intervention group had a significantly lower proportion of days absent due to illness compared with the control group (0.77% vs. 1.73%).

Food Preparation

Given the high transmissibility of enteric agents in a child care setting, much attention must be given to procedures involving food preparation. Areas for food preparation and storage should be separate from diapering

and toileting areas. Food should not be brought into diapering and toileting areas. Ideally, there should be separate personnel for food handling and caregiving. This may not be possible in smaller child care or family home settings. If this is the case, then food preparation should occur before handling any diapers, and hand hygiene should be practiced diligently. Hands should be washed with soap before handling food. If any personnel has illness concerning for an enteric pathogen (vomiting, diarrhea, jaundice), infectious skin lesions that cannot be covered, or difficult-to-control respiratory secretions, they should not be preparing food.¹⁴

Immunization and Screening of Children and Staff

Primary immunizations in infants and toddlers have greatly reduced many of the infectious illnesses that were easily transmitted among children in closed settings decades ago. The vaccine-preventable diseases for a preschool child are diphtheria, tetanus, pertussis, polio, influenza, measles, mumps, rubella, varicella, rotavirus, *H. influenzae* infection, *S. pneumoniae*, hepatitis A, and hepatitis B infections. Studies have shown that children who attend registered child care facilities are more likely to be up to date in their immunizations than are children cared for at home.¹⁴⁸ Laws requiring age-appropriate vaccination of children attending licensed child care programs exist in almost all states. Children should be immunized appropriately for age before entering child care, unless there is a medical contraindication or exemption for religious or philosophical reasons.

Employees and volunteers should have a health assessment before initiating work with children. This includes documenting and updating records of immunizations or immunity to HAV and HBV, measles, mumps, rubella, varicella, diphtheria, tetanus, polio, pertussis (to include one dose of acellular pertussis), and influenza. Recommendations for vaccination of children and adults are updated regularly by the Advisory Committee on Immunization Practices.⁷ Staff should receive annual influenza vaccinations, especially because young infants are a most vulnerable population for significant morbidity with influenza illness.

Before initiating work in a child care setting, adult and adolescent staff should be screened for tuberculosis (TB) by skin testing or a blood interferon- γ release assay. If the initial screening is negative, those at

risk should have annual TB testing. If positive, a chest radiograph should be performed and the staff member evaluated and cleared by a health care provider or public health official before beginning child care activities.^{14,16}

Exclusion Policy

The use of exclusion policies for specific infectious illnesses reflects not only risk for transmission to others but also the recognition that when children have moderate to severe illnesses, they may require more individualized care. When stool is not easily contained in a diaper, or toilet-trained children have accidental stooling because of diarrhea, transmissibility of enteric pathogens increases significantly. Similarly, respiratory agents shed in secretions are readily transmissible through coughing, sneezing, or contamination of hands or environmental surfaces. Even more increased attention to personal, hand, and environmental hygiene is necessary.¹⁴

The indications for exclusion of children from child care and their subsequent return to care vary based on the infection. In some cases children known to have highly infectious illnesses should not be allowed to attend child care until treatment is initiated (e.g., group A *Streptococcus* [GAS] infections), the symptoms have resolved (e.g., diarrhea caused by *Shigella*, rotavirus, or *Giardia*), or transmissibility has waned, as in pertussis, varicella, measles, and mumps. In addition, there are certain symptom complexes for which children should be excluded if the specific pathogen or the contagiousness of their illness is unknown (e.g., if a child has a high fever and a rash or diarrhea of unknown etiology). A list of recommendations for exclusion is presented in Table 248.2. There are some children attending group child care who remain unimmunized or underimmunized because of either contraindications for health reasons (e.g., immunocompromised state) or exemptions for a family's philosophical, religious, or personal beliefs. In the event of an outbreak of a vaccine-preventable disease (such as measles), these children should be excluded from child care until return is indicated by disease-specific guidelines and decisions made in conjunction with public health officials.^{14,15} There are conditions that do not necessarily require exclusion from child care. These include (1) asymptomatic excretion of some

TABLE 248.2 Recommendations for Temporary Exclusion From Child Care for Infections

Symptom Complexes	Infectious Etiology	Temporarily Exclude?	If Excluded, Readmit When
Illness that prevents child from participating comfortably in activities		Yes	Exclusion criteria are resolved and child is able to participate without compromising staff's ability to care for other children
Illness that results in a greater need for care than the program staff can provide without compromising their ability to care for other children		Yes	
Other health conditions that may indicate severe illness (e.g., severely ill appearance, fever, lethargy, lack of responsiveness, persistent crying, difficulty breathing or quickly spreading rash)		Yes	
Abdominal Pain	<i>Viral</i> <i>Bacterial</i> Group A <i>Streptococcus</i> pharyngitis	No, unless: Severe pain causing child to double over or scream Bloody/black stools No urine output for 8 h Diarrhea Vomiting Jaundice Fever with behavior change Looks or acts very ill	Pain resolves Able to participate Exclusion criteria are met

Continued

TABLE 248.2 Recommendations for Temporary Exclusion From Child Care for Infections—cont'd

Symptom Complexes	Infectious Etiology	Temporarily Exclude?	If Excluded, Readmit When
Cold symptoms: e.g., runny nose, scratchy throat, coughing, sneezing, watery eyes, fever	<i>Viral</i> Adenovirus Coxsackie virus Enterovirus Parainfluenza virus Respiratory syncytial virus Rhinovirus Coronavirus Influenza <i>Bacterial</i> Mycoplasma <i>Bordetella pertussis</i>	No, unless: Fever accompanied by behavior change Looks or acts very ill Difficulty breathing Blood-red or purple rash not associated with injury Meets other exclusion criteria	
Conjunctivitis	Bacterial Viral	No, unless child meets other exclusion criteria	For bacterial conjunctivitis: after parent has discussed with health professional Antibiotics may or may not be prescribed Exclusion criteria are resolved
Cough	Upper respiratory infection, usually viral Sinus infection, usually viral but may be bacterial Lower respiratory infection, usually viral but may be bacterial Croup, viral Pertussis	No, unless severe cough, rapid or difficult breathing, wheezing if not already evaluated and treated, cyanosis	Exclusion criteria are resolved
Fever	Viral Bacterial Parasitic	No, unless: Behavior change Unable to participate Care would compromise staff's ability to care for other children	Able to participate Exclusion criteria are resolved
Diarrhea	Usually viral Bacterial Parasitic	Yes, if: Stool is not contained in the diaper Diarrhea is causing "accidents" for toilet-trained children Stool frequency exceeds two or more stools above normal for that child Blood or mucus in stool Black stool Dry mouth No urine output in 8 h Jaundice Fever with behavior change Looks or acts very ill	Diapered children have their stool contained by the diaper Toilet-trained children do not have toileting accidents Stool frequency is fewer than two above normal for that child Able to participate without compromising staff's ability to care for them Cleared to return by health professional for all cases of bloody diarrhea and diarrhea caused by Shiga toxin-producing <i>E. coli</i> , <i>Shigella</i> , <i>Salmonella</i> , <i>Cryptosporidium</i> , or <i>Giardia</i>
Mouth sores	Oral thrush (candida) Herpes simplex virus Enterovirus (e.g., Coxsackie virus)	No, unless: Drooling steadily because of mouth sores Unable to participate Care would compromise staff's ability to care for other children	Able to participate Exclusion criteria are resolved
Rash	Viral Skin infections and infestations (i.e., scabies, ringworm) Severe bacterial infections: <i>N. meningitides</i> , <i>S. pneumoniae</i> , <i>S. aureus</i>	No, unless: Rash with behavior change or fever Has oozing or open wound Bruising not associated with injury Joint pain with rash Unable to participate Tender, red area of skin, particularly if increased in size or tenderness	Able to participate in activities On antibiotic (see indications for specific etiologies) Exclusion criteria are resolved
Sore throat	Viral Group A <i>Streptococcus</i>	No, unless: Unable to swallow Excessive drooling with breathing difficulty Fever with behavior change Child meets other exclusion criteria	Able to swallow Able to participate On medication at least 24 h for strep throat Exclusion criteria are resolved
Vomiting	Usually viral	Yes, if: Vomited more than two times in 24 h Vomiting and fever Green or bloody emesis No urine output in 8 h Looks or acts very ill	Vomiting ends Able to participate Exclusion criteria are resolved

enteropathogens, (2) purulent or nonpurulent conjunctivitis, (3) a rash without a fever or behavioral change, (4) CMV infection, (5) the carrier state of HBV infection, (6) HIV infection, and (7) parvovirus B19 infection in an immunocompetent host. For many infections, the highest risk for transmission of disease occurs before the appearance of recognizable symptoms. After illness occurs, other children already have been exposed, and exclusion is a less effective strategy. For this reason, exclusion has not been shown to be successful in reducing the frequency of viral upper respiratory tract infections.

Prophylaxis of Close Contacts

Prophylaxis is a strategy that may be useful in the management of some infections that occur in child care centers. For example, if a child has had invasive disease caused by *N. meningitidis*, rifampin prophylaxis for all child care contacts may prevent secondary or associated cases. If a child has pertussis, exposed children may be protected by a booster immunization, if appropriate, and administration of a macrolide for prophylaxis. During community epidemics, vaccination can be used as a strategy to prevent secondary infections. For example, immunization with MMR vaccine can be successful in terminating epidemics of measles in elementary or high schools. Varicella vaccine also can be used throughout a community and up to 3 days after exposure to curtail the spread of disease.

Education

An integral part of the control of infection within a child care center is education of families and staff (including caregivers and custodians). The staff must understand the general principles of transmission and control of infections. Education before job placement and frequent in-service trainings reinforce the importance of some basic techniques, especially hand hygiene. Supervision is essential to ensure compliance with policies.¹⁷⁶

Parents should be educated regarding recognition of illness, especially illnesses for which the child would receive the best care and attention at home or at a facility for ill children. The rationale and importance of compliance with child care center rules should be emphasized. The child care program should inform parents of the need to share information about communicable illnesses in the child or a family member.

INFECTIOUS AGENTS IN CHILD CARE

Infections Spread by the Respiratory Route

Upper Respiratory Infections

Respiratory viruses (rhinovirus, coronavirus, respiratory syncytial virus, human metapneumovirus, parainfluenza viruses 1 to 4, influenza viruses A and B, and adenoviruses) are the most common causes of infection in preschool-aged children.^{33,101,115,292} The range of clinical manifestations includes asymptomatic infection, simple upper respiratory infection (rhinitis), acute otitis media, pharyngitis, croup, tracheitis, bronchiolitis, and pneumonitis. Disease may be mild or severe and involve a single level or more than one level of the respiratory tree. Human bocavirus, first characterized by molecular analysis in 2005, has been identified in the respiratory tract of children with respiratory illness. However, more than 80% are identified in the setting of viral coinfection using molecular techniques.³⁰⁰ Bocavirus is also present in asymptomatic shedders. Its role as a pathogen has yet to be fully elucidated.^{42,163,196,300} Children may experience multiple infections with the same agent because of antigenic diversity within virus subtypes (e.g., influenza A virus), existence of multiple subtypes (e.g., rhinoviruses, coronaviruses), and failure of immunity to develop after a single exposure (e.g., respiratory syncytial virus). Viruses are shed from the site of infection (conjunctiva, nose, throat), even before clinical symptoms develop, thereby rendering control of the spread of these infections in child care difficult. Documentation that children in out-of-home child care (large family or other child care centers) experience more respiratory infections than those noted in children in home care is ample.^{94,111,154,189,190,208,209,259,263,284}

The availability of molecular techniques for viral identification has improved the ability and sensitivity of detecting viruses in respiratory secretions that may be pathogens or colonizers. In a 2-year longitudinal study of 225 children from three child care centers, Martin and colleagues

identified more than one virus in 47% of specimens (455 total) that were obtained at the time of mild or moderate illness. Only one virus was detected in 32% and none in 18%.¹⁹⁷

Bacterial coinfection causing complications can occur with viral upper respiratory infection. The most common complication is acute otitis media. Sinusitis, pneumonia, and meningitis are more invasive complicating infections. The overall incidence of these complications has dramatically decreased with the implementation of universal vaccination with conjugated Hib in 1987²⁴⁸ and conjugated pneumococcal vaccines in 2000 and 2010.

The peak age incidence of acute otitis media is between 6 and 18 months, similar to that of viral upper respiratory tract infections. Most children have had at least one episode of acute otitis media by the time they reach their second birthday, and approximately one-third will have had at least three episodes by that time.²⁷¹ Not surprisingly, because the frequency of episodes of viral respiratory infections is increased in children attending out-of-home child care, these children experience a notable increase in the frequency of episodes of otitis media.^{228,259,262,263,284} Two reviews strongly supported the notion that attendance at child care is a major risk factor for acquiring acute otitis media.^{233,279} Wald and colleagues²⁸⁴ provided data indicating that the risk for hospitalization for performance of myringotomy with tube placement was highest for children in large child care environments. Similarly, the risk for contracting recurrent acute otitis media and persistent middle-ear effusion also is higher for children in child care than for those who receive care at home.^{83,108,260,275} Researchers do not recommend that children with mild respiratory infections or otitis media be excluded from child care or be separated from the group of well children unless they act systemically ill or have fever with behavior change, difficulty breathing, purpuric or petechial rash, severe cough, or cyanosis.¹⁴ Furthermore, the strategy of exclusion from child care for mild respiratory illnesses has not been shown to achieve an overall reduction in infections for children in child care facilities.

Systemic Viral Infections

Parvovirus B19. Parvovirus B19, the etiologic agent of erythema infectiosum, or fifth disease, is spread by the respiratory route. Typically, the virus infects and destroys red blood cell precursors until the virus is neutralized by the development of antibody. Viral replication, viremia, and nasopharyngeal shedding occur approximately 1 week before the development of clinical symptoms. This benign disease of childhood (in a normal host) may occur in preschool- and school-aged children. The classical clinical illness is characterized by an erythematous rash on the face that gives a “slapped-cheek” appearance. This rash may follow 1 to 3 weeks after a mild, nonspecific illness with fever, myalgias, and headache. This maculopapular rash begins on the proximal ends of the extremities extending to the distal portions and trunk. After several days, these lesions may develop into a lacy reticular pattern and then fade. Infection can be asymptomatic in as many as 50% of children.

Less typical presentations include the papulopurpuric gloves-and-socks syndrome and rubelliform or petechial rashes. A community outbreak of parvovirus with petechial rash among children in Wisconsin has been described.⁹⁷ Children who are immunosuppressed may develop a more chronic infection resulting in a severe anemia because of the delayed clearance of the virus. Similarly, children with hemolytic disorders such as sickle cell disease can develop profound anemia during the period of aplasia.

The clinical importance of parvovirus B19 in the context of child care infections is transmission from an infected preschool-aged child to a pregnant mother or child care provider.¹²¹ Infection of the fetus may lead to nonimmune hydrops secondary to infection of erythrocyte progenitor cells. Estimates of fetal loss when a pregnant woman of unknown antibody status is exposed to parvovirus are 2.5% after household exposure and 1.5% after occupational exposure in a school or child care facility.²³

Children are not excluded from group child care when rash is present as they are no longer contagious. Children need not be excluded from child care unless other exclusion criteria are met (i.e., fever with behavior change). However, an infected child who has a blood disorder or is immunocompromised can shed large amounts of virus

and should be excluded.^{14,274} Routine exclusion of pregnant women from a child care center where erythema infectiosum is identified is not recommended.^{15,138}

Hand-Foot-and-Mouth Disease. Hand-foot-and-mouth disease (HFMD) is a clinical syndrome characterized by a vesicular exanthema on the distal parts of the extremities and mild stomatitis. Infections are often asymptomatic or mild, but they can be associated with fever and significant pain with the vesicles. Severe stomatitis can lead to dehydration. HFMD is most commonly caused by the enteroviruses Coxsackie A16 and enterovirus 71, although other enteroviruses have been identified. Transmission is person to person through contact with infected saliva, vesicles, respiratory secretions, or stool. Outbreaks usually occur during summer or autumn months in the United States. Two outbreaks of Coxsackie virus A16 HFMD have been reported in children attending child care.^{106,107} In recent years, outbreaks of HFMD associated with Coxsackie virus A6 have been described worldwide; one outbreak in four geographically distinct states in the United States related to Coxsackie A6 occurred during winter months. Of the 63 cases, 34 were in children younger than 2 years. The symptoms were more severe than those usually associated with Coxsackie virus A16.⁵⁹ The most significant clinical concern is the acquisition of Coxsackie virus infection during pregnancy, which may lead to spontaneous abortion.^{107,214} Exclusion from group child care is not routinely recommended because symptomatic and asymptomatic children may shed virus in stool for several weeks.¹⁴

Local Bacterial Infections

Streptococcus pyogenes or Group A Streptococcus. GAS is a frequent cause of respiratory and skin infections. The most common expression of infection with GAS is the development of pharyngitis and fever in a school-aged child. Usually, the throat infection is accompanied by tender anterior cervical nodes. In classical infection, none of the usual signs of viral upper respiratory disease—coryza, cough, and conjunctivitis—are present. This classical presentation, however, is rare in children younger than 3 years. Streptococcal infection of a preschool-aged child more often takes the form of a protracted upper respiratory infection. More typically, these patients have low-grade fever, persistent nasal discharge, anorexia, and cervical adenopathy. Given the rarity of rheumatic fever in young children, it is recommended to not test these young children unless they have contact with an older sibling with GAS infection or an outbreak is present.²⁵²

Although exposure of child care attendees to an index case of streptococcal pharyngitis can be assumed to result in secondary cases, relatively few epidemics of GAS infection have been reported in child care facilities.^{103,152,254} An outbreak occurred in a child care center in which preschool children shared facilities with kindergarten children in an after-school program. During a 3-month period, 47% of the child care population had positive pharyngeal cultures for GAS or positive results on a rapid antigen-detection test.²⁵⁴

GAS can also be transmitted person to person by skin-to-skin contact and colonize healthy skin. Superficial infection (impetigo) may then occur at sites of traumatized skin (e.g., insect bites or scratches). Often GAS and *S. aureus* are both isolated from sites of impetigo. Erysipelas and cellulitis due to GAS can result in an abrupt onset of fever and dramatic cutaneous erythema and tenderness often accompanied by regional adenopathy. Outbreaks of perianal cellulitis have been reported from child care centers.^{206,239} A cluster of 12 cases of perianal cellulitis, characterized by a well-demarcated rash around the anus with itching, rectal pain, blood-streaked stools, and occasionally a purulent discharge, was reported from a kindergarten setting in Denmark.²²⁰

The diagnosis of streptococcal skin infection can be made by careful performance of wound or surface cultures (obtained after carefully cleansing the area around the lesions) or examination of tissue aspirates. Spread of typical impetigo occurs commonly within families and presumably also would occur within child care centers. Children with GAS infections of the throat or skin should be excluded from group child care for 24 hours after the initiation of appropriate antibiotic treatment.^{14,15}

Invasive Bacterial Disease

Kingella kingae. *K. kingae* is a fastidious gram-negative coccobacillus that colonizes the oropharynx and is becoming increasingly recognized

as an important cause of osteoarticular infections in young children (<4 years).^{37,96,296} It has also been identified in cases of bacteremia and endocarditis.^{96,295} Colonization rates are highest in children younger than 2 years. Similar to other bacterial pathogens, the organism colonizes the upper respiratory tract of young children. The presence of different strains changes over time. The tonsils are identified as the primary site for colonization. Preceding stomatitis and upper respiratory viral infections have been recognized as risk factors for invasive disease.^{21,96} Disrupted mucosa may provide entry into the bloodstream, increasing the risk for disease at distant sites. Children with osteoarticular disease may often present subacutely, with symptoms related to the affected limb, but with low-grade or no fever and elevated inflammatory markers.

Methods of diagnostic detection have improved over the past several years, including the ability to identify *K. kingae* by molecular techniques. This has contributed to the increase in identification of this pathogen in clusters of infection. In-depth studies from Israel have identified *K. kingae* as the most common microbe causing osteoarticular infections in children aged 6 months to 3 years.^{299,96}

K. kingae can persist in the upper respiratory tract of asymptomatic children over long periods of time. Studies have demonstrated that the absence or presence of colonizing bacteria is variable and strains may replace one another over time.²² *Kingella* carriage rates in the general population are estimated to be 3% to 17%.^{64,96,297} Outbreaks of osteomyelitis and septic arthritis associated with *K. kingae* have been reported in child care settings in Minnesota,¹⁷¹ France,³⁷ and Israel.^{296,298} In 2007, a cluster of cases in a child care center in North Carolina was reported associated with a case of endocarditis. Genetically similar *Kingella* isolates were obtained from symptom-free children in the same child care.²⁴⁴ Colonization rates in these child care centers ranged from 7% to 42%. Bidet and colleagues described the first European cluster of *Kingella* osteoarticular infections. There were five child care attendees out of 24 who presented with arthritis or osteomyelitis in a 1-month period in France. The colonization rate among children who were not receiving antibiotics was 46% to 53%.^{32,37}

Neisseria meningitidis. *N. meningitidis* is a gram-negative, polysaccharide-encapsulated diplococcus that colonizes the nasopharynx. With the reduction of invasive HIB and *S. pneumoniae* disease because of effective immunization strategies, *N. meningitidis* is a leading cause of bacterial meningitis in the United States. Type B is the predominant subtype in the United States.¹⁹³ Meningococcemia is a major manifestation of invasive meningococcal disease with significant morbidity. Less commonly, pericarditis, pneumonia, arthritis, otitis media, or epiglottitis can occur. Active surveillance (2006–12) in the United States observed the highest rates of invasive meningococcal disease among infants younger than 1 year, although the case-fatality rate was the lowest in this age group. Hematogenous dissemination from the colonized nasopharynx may result in invasive disease. Transmission is person to person through infected respiratory droplets. Household contacts exposed to patients with meningococcal disease have a significantly higher risk for acquiring infection than does the general population.^{203,205}

Most cases of meningococcal disease are sporadic; however, there are several reports of outbreaks in closely grouped communities, including military barracks and college dormitories. In addition, the risk for acquiring secondary disease caused by *N. meningitidis* is increased in the child care setting.^{160,185,212,234} In a Belgian report,⁸⁸ exposure in a child care nursery during a prolonged meningococcal epidemic conferred a risk for infection that was 76 times greater than that in children of similar age who received care at home.

Prompt institution of chemoprophylaxis with rifampin is the recommended strategy for management of all intimate child contacts of a person with invasive *N. meningitidis* disease to prevent development of secondary or associated illness. A single oral dose of ciprofloxacin or azithromycin or an intramuscular dose of ceftriaxone is an alternative for adult contacts. Pregnant women should not receive rifampin or ciprofloxacin. Throat culture to identify those who would require prophylaxis is not recommended. In addition to household and other high-risk contacts, all child care contacts (children and adults) of an index case with meningococcal disease within 7 days of onset should receive chemoprophylaxis.¹⁵ In an outbreak, meningococcal conjugate vaccine may also be used for prevention of secondary cases if the outbreak serotype

is one that is contained in the vaccine and the contacts are in an appropriate age group for immunization.¹⁵ Management of exposures and outbreaks should be performed in conjunction with public health officials.

As of this writing, six vaccines are licensed in the United States for *N. meningitidis*. Four contain components against the serogroups A, C, Y, and W135, three of which are conjugate vaccines licensed to begin a primary series during infancy. In 2014 and 2015, two recombinant serogroup type B vaccines were approved for use in children and youth aged 10 to 25 years.¹⁹⁴

Children with meningococcal disease should be excluded from child care until they have received antimicrobial treatment for at least 24 hours.

Mycobacterium tuberculosis. Infection caused by *M. tuberculosis* in a preschool-aged child is a sentinel event. It represents the exposure of that child to an adolescent or adult with active tuberculosis disease. Children this young are much less likely to have cavitory lesions in their lungs and thus are less likely to be contagious. The identification of an infected child should prompt a public health investigation to identify the index case. Cases of tuberculosis in children have been traced to attendance at child care.^{122,186,211} Children identified as having active tuberculosis may attend group child care if public health officials have approved and determined that (1) they have started and are adherent to therapy, (2) they are noninfectious, (3) their symptoms have decreased, and (4) they are able to participate in the activities of the child care center. Children with latent TB disease are not contagious and do not need to be excluded from group child care.¹⁵ Screening of personnel who work in child care settings, including both staff and volunteers at high risk for exposure to TB, is essential to prevent tuberculosis in childhood. Child care staff members diagnosed with active TB disease are excluded from caring for children until they are determined to be noncontagious.¹⁵

Infections of the Gastrointestinal Tract

Parasitic Infections

Giardia lamblia. *G. lamblia* is the most common intestinal parasite of humans and a major cause of diarrhea in child care centers.^{39,227,243} Infection can be caused by the ingestion of as few as 10 cysts. Transmission is fecal-oral and most commonly results from person-to-person spread, although waterborne outbreaks have been documented.¹⁶⁹ Parents of child care attendees are at risk for acquiring infection.²²³ Asymptomatic excretion does occur and is most common in children younger than 3 years.^{30,224,227} Demonstration of *G. lamblia* cysts on environmental surfaces indicates additional potential for transmission.⁷¹ Cysts can remain infective on cool, moist environmental surfaces or in cool waters for months, increasing the chance of ingestion. Infection with this parasite causes infestation of the duodenum and proximal jejunum and results in asymptomatic carriage more often than clinical disease.¹⁵⁸

After an incubation period of approximately 2 weeks, symptomatic patients experience diarrhea, intermittent abdominal pain, anorexia, and flatulence. The most notable feature of the infection is its tendency to become protracted, thereby leading to weight loss, failure to thrive, and anemia. Diagnosis is made by identifying organisms using sensitive and specific enzyme immunoassays or direct fluorescent antibody assays of stool samples. Occasionally, trophozoites or cysts are identified by microscopic examination of stool or duodenal aspirates. Treatment is not recommended for asymptomatic individuals shedding *G. lamblia* cysts. For symptomatic individuals, treatment may be undertaken. Relapses occur in approximately 15% of patients, often requiring a second course of treatment. After resolution of symptoms, either by virtue of treatment or by spontaneous cure, patients may continue to shed cysts for a very long time.^{158,224}

Children are excluded from group child care if there is diarrhea present that is not contained in the diaper or causes accidents in older children or if the child cannot participate in center activities. Follow-up testing is not required if the child or staff member does not have diarrhea.

Cryptosporidium. *Cryptosporidium* parasites (primarily *C. parvum* and *C. hominum*) have been mainly identified as an opportunistic infection causing diarrhea in immunocompromised hosts. Infection usually results in self-limited illness in immunocompetent children and adults.⁷³ The usual clinical symptoms are frequent watery diarrhea that

may be associated with low-grade fever, abdominal pain, and weight loss. Vomiting occurs in approximately 30% of patients. The illness is usually self-limited in healthy individuals, although the diarrhea can last as long as 2 or 3 weeks. Oocysts can be shed in stool of immunocompetent individuals up to 60 days after gastrointestinal symptoms resolve.¹⁶⁴

Cryptosporidium oocysts can be found in the soil, water, or food or on surfaces contaminated by feces. Transmission is fecal-oral. The most common source of transmission and outbreaks has been the ingestion of contaminated water (either drinking or recreational exposure).¹⁹² Increased incidence of cryptosporidiosis occurs during summer and early fall months corresponding to months with increased recreational water activities.⁵⁸ The oocysts can survive chlorine in water treated at recommended levels for recreation.²⁵⁰ In 2011–12 more than half (52%) of the reported 69 outbreaks of diarrhea associated with treated recreational water in the United States were due to *Cryptosporidium*.¹⁵⁰ Like *G. lamblia*, *Cryptosporidium* has a very low infectious dose for humans. Infection can occur with as few as 10 to 30 oocysts.⁶⁷ Spread of infection is facilitated in child care centers because oocysts shed in the feces of infected persons are highly resistant to common disinfectants. Many outbreaks of diarrhea caused by *Cryptosporidium* have been reported from child care centers.^{11,12,72,77,142,270} Asymptomatic children and adults shed oocysts for weeks after infection.

The diagnosis is made by examination of stool for oocysts by direct immunofluorescent antibody method. Direct microscopy can be performed with special stains such as the modified Kinyoun acid-fast stain. Alternative methods include enzyme immunoassays specific for *Cryptosporidium* antigen. Routine stool examinations for ova and parasites can miss the *cryptosporidium* oocysts. Generally, treatment is not required for immunocompetent individuals. The recommended treatment is a 3-day course of nitazoxanide for anyone aged 1 year and older. Treatment can reduce the duration of diarrhea and shedding of oocysts in stool.¹³

Exclusion from child care is recommended if stool cannot be contained in the diaper, older children are having accidents, stool frequency is 2 times or more above normal for that child, blood or mucus is found in the stool, or child is not able to participate in usual activities of the child care center. This latter situation causes excess work for staff and may compromise care of other children.

Bacterial Pathogens

Shigella. Infection with *Shigella* organisms causes illness of variable severity but easy transmissibility. Accordingly, *Shigella* is one of the most common causes of diarrhea outbreaks in the child care population.^{48,25,120} Infection can be caused by as few as 10 organisms. Fecal-oral transmission is the primary mode of transmission. *Shigella* organisms can survive in water for up to 6 months as well as on food, and have been implicated in both water-borne and food-borne illnesses. There are four species (*S. sonnei* [the predominant species in the United States], *S. flexneri*, *S. dysenteriae*, and *S. boydii*) responsible for human shigellosis.

Shigellosis is primarily a disease of young children. In the US reporting of laboratory-confirmed infection, the highest incidence rates are among children age 4 years and younger. Younger children have the highest attack rate during outbreaks and are the most effective transmitters of infection.²⁷³ Child care personnel and family contacts also experience high attack rates.^{151,269} Surveillance data from the National Outbreak Reporting System (NORS) identified *Shigella* as the most common bacterial etiology of outbreaks of acute gastroenteritis spread person to person in 2009–10.^{135,290} Of the 2259 outbreaks reported, 4% were caused by *Shigella*, and of those with reported settings ($n = 30$), nearly all (97%) were in child care centers.²⁹⁰

After an incubation period of 1 to 3 days, fever and watery diarrhea, followed by crampy abdominal pain, tenesmus, and mucoid bloody stools, occurs in patients with classical disease. In many cases, the illness is mild and self-limited, is indistinguishable from other causes of gastroenteritis, and often does not require treatment.

Stool culture for *Shigella* is diagnostic. Detection of *Shigella* by multiplex nucleic acid techniques is also becoming more available. Treatment of shigellosis with an appropriate antimicrobial effectively

terminates the illness. Antimicrobial treatment decreases the duration of symptoms and fecal shedding. Untreated persons continue to excrete organisms for several weeks. Susceptibility varies both within and outside the United States, and therefore testing of stool isolates is indicated. Isolates with increasing resistance to ampicillin and trimethoprim-sulfamethoxazole are being reported. Therefore it is important to isolate the organism and determine susceptibility in order to provide optimal treatment.^{25,161}

It is essential that child care centers and health professionals work with public health agencies in evaluating and managing outbreaks. Symptomatic staff and attendees should have stool cultured if a case of *Shigella* is identified. Children or staff with confirmed *Shigella* infection should be excluded. They can return to child care when diarrhea has stopped for at least 24 hours. Some states may require a negative stool culture obtained after 24 hours of diarrheal cessation before a child care staff or attendee may return.^{14,15}

Salmonella. *Salmonella* is the most common cause of bacterial diarrhea in many parts of the United States and is the cause of numerous outbreaks a year. The most common serotypes are *Salmonella* serovars *typhimurium*, *enteritidis* and *newport*. Infection usually occurs after the ingestion of contaminated food or beverages and has also been reported after contact with colonized reptiles such as turtles.^{139,285} These modes of transmission underscore the importance of hand hygiene, proper food handling and cooking, and avoiding exposure of preschool children to reptiles and amphibians. Person-to-person spread seldom occurs, except in infancy, when the infective dose is low.²⁹³

The most common expression of infection with *Salmonella* is uncomplicated gastroenteritis. The illness begins approximately 12 to 36 hours after exposure and often is characterized by initial vomiting followed by diarrhea. Abdominal pain and fever are frequent accompaniments; occasionally, stools contain mucus and blood. Although most cases are self-limited, *Salmonella* infection can be distinguished from other causes of gastroenteritis by its occasionally protracted course. Nearly half of children younger than 5 years may excrete *Salmonella* organisms up to 3 months after infection. Infants younger than 1 year have the highest incidence of invasive *Salmonella* disease in the United States. Children younger than 4 years have the highest age-specific incidence of nontyphoidal *Salmonella* infection in the United States.¹⁵

The diagnosis is made by stool culture. In general, antimicrobials are not recommended for those with asymptomatic nontyphoidal *Salmonella* infection or uncomplicated gastroenteritis. Antimicrobial therapy can prolong the duration of fecal shedding of organisms. Management of certain hosts, such as neonates and immunocompromised patients, is controversial. Although some experts recommend antimicrobial therapy for these groups, few data support this recommendation.

Exclusion from child care is recommended if diarrhea cannot be contained in the diaper of a diapered child or if an older child has accidents. When stools are normal, little reason exists to restrict attendance. Obtaining stool cultures from asymptomatic contacts is not necessary for nontyphoidal *Salmonella*. If *Salmonella typhi* or *paratyphi* is identified in the stool of a child or staff member, they should be treated and excluded until three stools obtained 48 hours or more after antibiotics end, are negative.^{14,15}

Clostridium difficile. *Clostridium difficile* is the classical cause of pseudomembranous colitis in patients who have received or are receiving antimicrobial agents, and it rarely causes disease unassociated with antimicrobial use. The organism, a gram-positive, spore-forming rod, is distributed widely in soil and in the gastrointestinal tract of humans. Infection is acquired by ingestion of spores from the environment or an infected person. Disease is a consequence of the elaboration of one or more toxins by vegetative organisms. Clinical symptoms include fever, diarrhea, and abdominal cramps. Stools may contain blood and mucus. The illness varies in severity from mild to life-threatening. Early studies demonstrated an increased association of *C. difficile* toxin with diarrheal disease during an evaluation of five outbreaks in three child care centers.^{172,173} During outbreaks of *C. difficile* diarrhea in child care centers, environmental contamination was increased, as was recovery of *C. difficile* from the hands of children and staff.¹⁷³

The epidemiology of *C. difficile* infection in the general population has changed dramatically since the early 2000s, with an increase in incidence and severity in adults. Epidemiologic studies of *C. difficile* in hospitalized children show similar trends.^{36,174,236} Population-based studies indicate that in children, 50% to 71% of cases are community-acquired infections.^{170,288}

The ability to identify the true incidence of *C. difficile* disease in children younger than 3 years is complicated by the fact that as many as 30% to 70% of infants younger than 1 year are colonized by toxigenic and nontoxigenic strains without signs of disease.^{26,162,181,235,278} This colonization rate decreases over the next 2 years of life. Children aged 3 years and older have the same rates of *C. difficile* infection as the general adult population (<3%).¹⁶²

Hand hygiene with the use of soap and water is important in the setting of an outbreak. The *C. difficile* spores are not inactivated by alcohol-based sanitizers. Children and personnel should be excluded from group child care until they are asymptomatic.

Shiga toxin-producing strains of Escherichia coli. Infection with Shiga toxin-producing strains of *E. coli* (STEC) is characterized by bouts of often bloody diarrhea and abdominal pain. The bacteria have the potential to cause significant morbidity in children. Approximately 5% to 10% of infected children develop hemolytic uremic syndrome (HUS). Hemorrhagic colitis is also a complication of this infection.

Ruminants such as cattle are the main reservoir for STEC. Transmission is fecal-oral. Infection occurs through ingestion of contaminated food or water or through direct contact with an infected person, carrier animal (such as in petting zoos), or contaminated fomites. Numerous outbreaks have occurred associated with raw meat, unpasteurized milk, contaminated foods, and recreational water.

The most common *E. coli* serotype causing illness is O157:H7. However, several other types have been associated with bloody diarrhea and with HUS.

Numerous STEC outbreaks have been reported in child care settings.^{10,35,226,257} In 1986, an outbreak of diarrhea caused by *E. coli* O157:H7 was reported from a child care center attended by 107 children.²⁵⁷ Thirty-four percent of attendees became ill, with a significant increase in risk for younger children. Approximately one-third of the children with diarrhea had bloody stools, and HUS developed in three children. Although infection with *E. coli* O157:H7 usually occurs after the ingestion of contaminated foods, person-to-person spread of infection most likely occurred in this epidemic. The diarrheal illness also was documented in family members of ill children.

Subsequent epidemiologic studies in Minnesota confirmed the mode of transmission for *E. coli* O157:H7 to be person to person in the child care setting.³⁵ Outbreaks of another strain with severe sequelae (*E. coli* O104:H4) have been reported in adults in Europe.¹¹³

A systematic analysis of 90 outbreaks occurring worldwide (1982–2006) identified about 20% of cases arising from secondary spread. The highest proportion of secondary cases was among children younger than 6 years.²⁵⁵

Antibiotic treatment has not been recommended for persons with diarrhea caused by *E. coli* O157:H7.²⁹⁴

Infected children should be excluded from group child care until diarrhea resolves and two stool cultures are negative (obtained 48 hours after any antibiotic treatment if used).¹⁵ Unfortunately, fecal shedding of *E. coli* O157:H7 may be quite prolonged in young children.²⁶⁷ Any symptomatic contact of a person with STEC should have stools cultured. In an outbreak situation, child care centers should be closed to new admissions. Control and management of outbreaks should be performed in conjunction with public health officials.

Viral Gastrointestinal Pathogens

Viral enteric pathogens are common causes of acute gastroenteritis in group child care settings. Norovirus has become the leading cause of acute gastroenteritis (AGE) since the widespread introduction of the rotavirus vaccine in 2006. It has been responsible for multiple outbreaks of AGE each year in the United States. The caliciviruses, norovirus and Sapovirus, are nonenveloped RNA viruses that have a worldwide distribution. Sapovirus is much less frequently an agent of gastroenteritis than is norovirus but has been implicated in child care outbreaks.¹⁴⁰

Transmission is by person-to-person spread through the fecal-oral route or through contaminated food or water. Noroviral particles found in vomitus are potentially infectious through the airborne route during forceful vomiting. Norovirus is antigenically diverse, therefore repeated bouts of diarrhea may occur with exposure to different viral variants. Norovirus is highly contagious; a very small inoculum is required to establish infection. Outbreaks frequently are observed in closed populations, including child care centers and on cruise ships. The attack rate usually is high. Several reports highlight the transmissibility of the Caliciviridae in the child care setting.^{126,157}

A cross-sectional survey in the Netherlands of the presence of stool pathogens in preschool child-parent pairs (907 households) was recently published. Monthly stool sampling for 16 enteric organisms with multiplex polymerase chain reaction (PCR) was performed along with symptom questionnaires and the collection of demographic data. The most commonly isolated viruses associated with child care attendance (52% of respondents) were the Caliciviridae (norovirus and Sapovirus). Clinical symptoms of AGE were significantly associated with norovirus II, astrovirus, and adenovirus 41.¹⁴⁵

Astroviruses are also common causes of diarrheal illness in child care. Outbreaks have been reported in child care settings^{9,253} and other closed populations. Children younger than 4 years are infected most commonly, and the illness has a winter predominance. Transmission is usually person to person by the fecal-oral route. This illness is indistinguishable from the other viral causes of gastroenteritis, presenting with watery diarrhea that may be accompanied by vomiting, fever, or abdominal pain. Healthy, symptom-free individuals can shed virus for several weeks.

Infections Spread by Skin Contact

Staphylococcus aureus

S. aureus is part of the endogenous flora of humans; the nose is the primary site of carriage in adults and children. At any one time, approximately 30% of people carry *S. aureus* in their anterior nares.¹⁹⁵ Transmission is primarily through person-to-person skin contact but also occurs through direct contact with contaminated environmental surfaces.

During the 1990s there was an increasing prevalence of disease caused by methicillin-resistant *S. aureus* (MRSA) in children without predisposing risk factors such as contact with the health care system.^{51,144} Studies of colonization in child care centers demonstrated likely transmission within the child care setting.^{1,146,245}

This community-acquired MRSA (CA-MRSA) has a genetic predisposition for causing skin and soft tissue infections (e.g., abscesses, carbuncles, and furuncles). More rarely, CA-MRSA causes severe invasive infections such as bacteremia, endocarditis, osteomyelitis, pyomyositis, or necrotizing pneumonia. Methicillin-susceptible strains of *S. aureus* (MSSA) cause similar clinical findings. Surveys of the incidence of CA-MRSA disease in hospital and community settings (including child care) have demonstrated the most rapid increase of infections among young children.^{78,116,204}

A survey of MRSA isolates derived from national databases of hospital discharges over a 10-year period from 1998 to 2007 demonstrated a 16-fold increase in hospitalization rates for CA-MRSA infections in children. The proportion of *S. aureus* abscesses caused by the CA-MRSA phenotype increased from 8.7% to 60.3% over this same time period.²⁰⁴ An epidemiologic survey (2001–02) using data from the Active Bacterial Core Surveillance program demonstrated the incidence of disease related to CA-MRSA was highest among individuals younger than 2 years. Of the 1647 patients with CA-MRSA isolates, 77% had skin and soft tissue infection.¹¹⁶

Children with documented MRSA should not be excluded from child care for colonization or for skin or soft tissue infections. Any open and draining wounds should be covered.

Scabies

Scabies is an infection of the skin caused by infestation with the female mite *Sarcoptes scabiei*. It is an obligate parasite that undergoes its complete life cycle in humans. Transmitted by person-to-person spread from an infested individual, the mite buries itself beneath the stratum corneum

and burrows along for its 30-day life span while laying two to three eggs per day. The larval and nymphal mites scatter after hatching to embed themselves in skin at distant sites. Some 3 to 6 weeks later, a pruritic eruption (worse at night) develops and leads to excoriation, bleeding, and crusting. The distribution of lesions varies with age. In adults and older children, the eruption, which consists of papules, vesicles, and nodules, occurs commonly in the interdigital spaces of the hands, on the extensor surface of the elbows, and around the umbilicus, waist, axillary lines, and genital area. In infants and young children, vesicular and eczematous lesions can be found on the hands and feet, as well as on the face and head.

Although scabies is spread primarily by close personal contact, skin-to-skin transmission can result from prolonged casual contact; this is observed in child care centers.²³⁸ Mites can survive on inanimate surfaces for 2 to 3 days, a period that permits transmission by fomites such as clothes, bed linen, and furniture. An outbreak of scabies was reported in a hospital-affiliated child care facility. Elimination of the problem required a coordinated effort with simultaneous treatment of all potentially infected individuals.²³⁸

The diagnosis is made by scraping the lesions and demonstrating the mite, ova, or mite feces. Treatment of the index case should be undertaken with a scabicide, preferably 5% permethrin in children older than 2 months. Lindane should not be used because of safety concerns. Asymptomatic contacts should be treated simultaneously because they may be infected unknowingly and may be capable of transmitting the mite during this asymptomatic period. Clothing and bed linens that had contact with the skin of infected persons during the 3 days before treatment should be laundered in hot water. Alternatively, items can be stored in plastic for at least 4 days.¹⁵

An infected child should be excluded from child care until treatment has occurred which is usually overnight.

Head Lice

Head lice (*Pediculus capitis*) infestation occurs commonly in children attending child care, preschool, and elementary school. It affects children of every socioeconomic status. The insect, a hemophagocytic ectoparasite, obtains nourishment by sucking capillary blood from the scalp. Female lice attach egg cases (nits) to the hair shafts at or very near the scalp. The eggs hatch 8 to 11 days later, and the louse nymphs are released.

The diagnosis is often made by close inspection of the scalp. Nits are observed readily, although live lice may be difficult to see, especially in light infestations.

Treatment is with topical pediculicides, used as directed with care. These include permethrin lotions and pyrethrin-based products. Resistance has been identified with these products. Additionally products such as malathion, benzyl alcohol lotion, spinosad suspension, or ivermectin lotion may be used. Lindane shampoo should not be used because of safety concerns.¹⁵ Nits can be removed mechanically with spiral combs.

Head lice is transferred by direct head-to-head contact and rarely by fomites such as hats, combs, clothing, or bedding. However, such items used by the infected person within 2 days can be washed in high temperatures (130°F [54.4°C]) and dried on a hot air cycle.¹⁵ If lice infestation is diagnosed in a child in child care, he or she should not be sent home early, but families of other children and the child's household should be notified so that they can be evaluated. Children with lice can return to child care after treatment has occurred.

Infections Spread by Contact With Blood, Urine, or Saliva

Cytomegalovirus

CMV is a common cause of infection in preschool-aged children. Most often, the infection is completely asymptomatic.⁹⁴ Rarely, the child may experience a febrile illness with lymphadenopathy and hepatosplenomegaly. In the United States, approximately 0.7% of newborns are infected with CMV in utero and shed virus at birth.¹⁶⁷ Of these, approximately 90% are symptom free.^{261,44} CMV is the leading known cause of sensorineural hearing loss in infants. Sources of CMV in the child care setting are infants and children who have been infected by their mothers by vertical transmission in utero, perinatally, or postpartum through breast-feeding (~6%). Infection in preschool-aged children leads to viral shedding into saliva and urine. Transmission likely

occurs by direct contact with infected saliva or through fomites (toys and blankets) contaminated with saliva, rather than by respiratory droplets.²⁵⁸ Shedding of CMV is as chronic among infected toddlers in child care centers as it is in children with perinatal or congenital infection.^{5,217,218}

Strangert and colleagues²⁶⁴ reported the isolation of CMV from 7 of 10 children between 21 and 30 months of age in one child care center. Strom²⁶⁵ found that 13 of 18 (72%) children between 24 and 36 months of age in a single nursery excreted CMV. Children younger than 3 years who acquire CMV after birth excrete CMV in urine and saliva for 6 to 42 months (mean, 18 months).⁵ Other investigators demonstrated that peak rates of infection occur in children between 1 and 3 years of age, when viral excretion may be documented in as many as 70% of children in child care.^{2,156,165,207,216,218}

Household contact is a common source of CMV in young children. A population-based study evaluating risk factors for CMV among 4 to 10 year olds in the United States participating in the NHANES III identified CMV status of household members (mother and siblings) to be a strong predictor of CMV seroprevalence in the child. In this study, previous child care attendance was not shown to be a significant predictor.²⁶¹

The greatest risk for morbidity is the acquisition of CMV during early pregnancy in child care providers or mothers of children attending child care.^{4,2,3,6} Such acquisition may lead to clinically evident congenital CMV infection (microcephaly, hepatosplenomegaly, chorioretinitis, psychomotor retardation, and deafness) in approximately 5% to 10% of infected children. Another 10% to 15% of infants experience occult, but potentially damaging, infection that results in milder degrees of hearing loss and learning disabilities.²⁵⁸ Because of the high rates of asymptomatic excretion by children, it is important for child care personnel to be aware of the risks of transmission and routinely practice appropriate hand hygiene.¹⁵

Herpes Simplex Virus

HSV is a DNA virus that commonly infects mucosal epithelial cells. Inoculation and replication at the site of infection are followed by the establishment of latency in sensory ganglia. Primary infection with HSV type 1 most often occurs in the oral mucosa. Approximately 15% of young children younger than 3 years will have gingivostomatitis as the manifestation of primary HSV-1 infection.^{20,65,240} Symptoms of primary infection range from asymptomatic to severe, painful ulcerations of the oral mucosa and perioral regions that can lead to dehydration in a child who is unable to swallow. Stomatitis may be accompanied by signs of upper respiratory infection, fever, pharyngitis, and regional lymphadenopathy. Reactivation of virus most often manifests as asymptomatic shedding of virus in the saliva or as the presence of labial ulcerations (i.e., cold sores). Other sites of recurrent lesions may be seen, such as herpetic whitlow resulting from a child autoinoculating his or her fingers through sucking. Children who have perinatally acquired HSV may have recurrent infections at sites related to the original infection.

Transmission in a group child care setting is through direct contact with herpetic lesions, or fomites contaminated with infected saliva. Studies have demonstrated high attack rates of HSV infection and stomatitis in orphanages^{65,132} and child care settings.^{240,177} One study of 90 children in a child care center (aged 0–37 months) in Japan identified four clusters of infection over the 4 years of observation. Horizontal transmission was confirmed by genetic analysis of the isolated viruses.¹⁷⁷

Children with herpetic gingivostomatitis do not need to be excluded from group care unless there is difficulty controlling drooling. Children and staff with recurrent infection do not need to be excluded. Covering recurrent lesions with clothing or bandages during child care is sufficient.¹⁵

Human Immunodeficiency Virus

The potential transmission of HIV by blood or body fluid exposure can cause great concern for families and staff. However, the risk for nonsexual, nonpercutaneous transmission is extremely low. Studies of risk to health care workers with percutaneous exposure to known HIV-infected blood by needlestick has been estimated to be less than

three in 1000 exposures.³⁴ To date, HIV infection has not been reported to be transmitted in a child care center.

There are rare case reports of transmission of HIV within households with an infected member.^{49,110,119,283} In most cases, transmission occurred in a setting with ongoing exposure of nonintact skin (e.g., eczema) or mucosal surfaces to infected blood or body fluids. Three children have been identified who were likely infected through the practice of pre-mastication of food by an HIV-infected caregiver. In two cases, the pre-mastication occurred at a time the caregiver was known to have had bleeding gums or mouth sores.¹¹⁹ In light of its rare horizontal transmission to nonsexual contacts within households with an infected member, HIV would not be expected to spread in child care settings.^{117,166}

One potential high-risk situation may involve HIV-positive children who are persistent biters or who have extensive weeping skin lesions. However, several reports indicate a lack of transmission to individuals bitten or scratched by a person infected with HIV.^{95,232,251,276} An incident was reported from London in which 21 elementary school-aged children repeatedly stuck themselves and their classmates with diabetic needles on the playground. When it was determined that one of the children was HIV positive with high viral load, 19 children received antiretroviral medication for postexposure prophylaxis. There were no HIV seroconversions.²⁷²

Since the institution of guidelines to identify HIV-positive women during pregnancy and intervene with peripartum antiretroviral medication,⁵⁰ the incidence of perinatal HIV infection in the United States has declined dramatically.⁵³ Recent estimates are that fewer than 200 infants are born in the United States with HIV infection. Children who are born in countries with high rates of HIV infection and immigrate or are adopted into the United States should be screened for HIV infection. Personnel should be trained in the use of standard precautions and use gloves for potential exposures to blood or body fluids. Blood and bodily fluid from everyone should be treated as if it potentially carries a blood-borne pathogen. Children who have weeping skin lesions that cannot be covered or bleeding problems should be excluded from child care until the problem is resolved.¹⁴

Vaccine-Preventable Diseases

Since the beginning of the vaccine era in the early 20th century, many of the infectious illnesses that were easily spread among children and household contacts are now significantly decreased in number. A comparison of annual morbidity of 10 infectious diseases for which universal vaccination is recommended for US children showed an approximately 95% to 100% decrease in morbidity for all infections (2007 vs. baseline 20th-century annual morbidity data).²²¹ Currently 14 vaccines are recommended for children in the United States before entry into elementary school. These provide protection to young infants and children through the development of individual and herd immunity. Because of the success of vaccine programs, fewer practitioners in countries with robust vaccine programs have seen the clinical manifestations of these infections. However, there continues to be a need for awareness of the clinical presentations of these diseases because unimmunized or underimmunized children (by family choice or because of immunocompromised status) may carry these organisms into or be exposed to them in group child care settings. States have differing regulations for vaccination exemptions by families for religious or philosophical reasons. Accordingly, rates of unimmunized children vary by geographic location. When outbreaks of vaccine-preventable illnesses do occur, public health officials should be notified and involved in management. Exclusion of unvaccinated children from child care may be recommended for their health and that of those who are unable to be immunized because of age or health status. Many infections are still present in high rates in other countries, and children born in these countries who immigrate may be asymptomatic carriers of infectious organisms (e.g., hepatitis A).

Diphtheria

Diphtheria is caused by production of toxin by the bacteria *Corynebacterium diphtheriae*. Clinical presentation may include nasal symptoms, membranous pharyngitis, obstructive laryngotracheitis, or skin manifestations. The prominent symptoms are usually a severe sore throat and croup accompanied by toxemia.

A probable case of diphtheria was reported in the United States in 2012.⁶² The case before that was reported in 2003. Diphtheria is still present and endemic in countries with low rates of vaccination and predominantly in tropical areas of the world. In 2014, more than 7000 cases were reported worldwide by the World Health Organization.

C. diphtheriae is spread by respiratory droplets after intimate contact with someone who is infected or is a carrier. Individuals are susceptible if they have not been immunized or have been immunized only partially. Treatment is with antitoxin and antibiotics (erythromycin or penicillin). Prophylaxis can be accomplished with erythromycin or penicillin if an individual is found to be a carrier. Immunization with a diphtheria toxoid-containing vaccine is effective in preventing disease and spread of infection.

Haemophilus influenzae Type B

Historically, Hib was the major bacterial pathogen of childhood and was responsible for many cases of meningitis, epiglottitis, pneumonia, facial cellulitis, and septic arthritis. These infections primarily occurred in children between 2 months and 5 years of age, with a peak occurring in those between 6 and 18 months of age. The organism colonizes the nasopharynx before becoming blood-borne; hematogenous dissemination results in a distant focus of infection. The bacteria are transmitted on respiratory droplets.

The availability and universal use of effective vaccines for the prevention of Hib infection have dramatically changed the epidemiology of infections caused by this pathogen.²⁴⁸ Conjugate vaccines were introduced in 1987. Although there has been a marked decline in invasive disease since then, cases of invasive Hib disease are still reported sporadically. The Active Bacterial Core Surveillance Report identified 11 cases of Hib invasive disease in the United States in 2013 and 12 cases in 2014, three were younger than 1 year.⁶³

Schulte and coworkers²⁴¹ reviewed the pattern of invasive Hib infection in New York State after the introduction of the conjugate vaccine. These investigators demonstrated a dramatic decline in the incidence of Hib disease in children younger than 5 years, among both those in child care and those in home care. In 2007, a voluntary recall of Hib vaccine by one supplier led to underimmunization of children younger than 15 months because immunization schedules required adjustment. The following year an increase in cases of Hib invasive disease (five children ≤ 3 years of age) was reported from the state of Minnesota (higher than in the previous 16 years). Of these cases, the majority of children were underimmunized because of parental refusal. Although cases were present, a simultaneous survey of nasopharyngeal carriage of Hib showed low rates of carriage in this age group.¹⁹¹

Rifampin is the medication of choice for prophylaxis of at-risk individuals exposed to a case of Hib disease. In the rare instance of invasive Hib disease in a child care center, public health officials should be involved in management. All personnel and child care attendees should receive rifampin prophylaxis if two or more cases of invasive Hib disease have occurred in the center within 60 days and unimmunized or underimmunized children attend. If only one case has occurred in the child care center, all attendees who are unimmunized or not completely immunized should be monitored carefully and be medically evaluated if ill or febrile.¹⁵ Children with Hib disease should be excluded until cleared by a health care provider.

Streptococcus pneumoniae

Pneumococci are a common cause of bacterial infections of the upper and lower respiratory tracts, including otitis media, sinusitis, and pneumonia.²⁴² As respiratory pathogens, they can also cause other upper respiratory tract infections, such as conjunctivitis, and important systemic illnesses, including occult bacteremia, bacteremic periorbital cellulitis, and meningitis.

S. pneumoniae is spread easily in the child care setting related to the high rates of nasal carriage in young children. It is transmitted on respiratory droplets. Numerous studies have demonstrated the horizontal transmission of *S. pneumoniae* and its relationship to nasal carriage among children in child care centers.

In 2000, a pneumococcal conjugate vaccine containing seven common serotypes of *S. pneumoniae* (PCV7) was licensed in the United States.

Subsequently, a reduction in nasopharyngeal colonization rates with the serotypes of *S. pneumoniae* contained in the vaccine was documented among young children.^{81,80,136} A secondary effect of the conjugate vaccines was the decrease of both colonization and disease among the contacts of vaccinees.¹²⁴

The implementation of PCV7 also had an impact on the rates of carriage and disease caused by penicillin-nonsusceptible strains.^{178,249} Active surveillance data from 1996 to 2004 demonstrated an 81% decrease in invasive disease caused by penicillin-nonsusceptible pneumococci in children younger than 2 years.¹⁷⁸ However, soon after the introduction of PCV7, replacement, non-PCV7 pneumococcal strains were identified in the nasopharynx of healthy, symptom-free children, and were also the cause of invasive disease (e.g., meningitis or bacteremia).^{79,147,219}

In 2010, a 13-valent pneumococcal conjugate vaccine was licensed that incorporated antigens of the more invasive pneumococcal serotypes including serotype 19A, which had emerged as a predominant non-PCV7 serotype often causing severe disease. PCV13 replaced PCV7 in recommendations for universal vaccination of infants.⁵⁷ Since then, several studies have documented a decrease in nasopharyngeal carriage in preschool children of PCV13 strains of pneumococcus,^{91,127} including nonsusceptible strains.⁸² Declining rates of acute otitis media,^{112,182,268} hospitalizations for pneumonia,^{128,129} and other invasive pneumococcal diseases such as meningitis¹³⁷ were demonstrated in multiple studies.

Children with pneumococcal disease (local or invasive) do not need to be excluded from child care unless they are unable to fully participate or require additional care by staff. There is no recommendation for chemoprophylaxis of contacts of an individual with pneumococcal disease.

Influenza

Influenza is a common cause of upper respiratory infection in preschool-aged children. The severity of infection is variable, from mild nasal congestion to a severe sepsis syndrome. Influenza can cause significant morbidity in people of all ages; children younger than 5 years carry a large burden of disease. Secondary lower respiratory tract infections with *S. aureus* or *S. pneumoniae*, among other pathogens, contribute to much of the morbidity in severe cases.

Influenza is transmitted person to person through infected droplets with a cough or sneeze, or indirectly from contaminated objects. Secondary transmission to household and child care contacts is a common occurrence.

Epidemics occur seasonally during the colder months of the year. However, in 2009 to 2012 a pandemic of influenza A (H1N1) strain was seen globally that began in the spring. During this pandemic there was an observed fourfold increase in mortality among children compared with previous years.⁶¹

Because of variation in influenza A antigens, components of influenza vaccines are adjusted annually. The antigens for H1N1 have subsequently been included in the seasonal vaccine. A trivalent inactivated influenza vaccine is recommended for seasonal immunization of persons older than 6 months.

Children with influenza should not be excluded from child care unless they are unable to participate, or if caring for the child would compromise the ability of staff to care for other children.¹⁴

Varicella

Varicella, or chickenpox, is a highly contagious infection that is spread easily by the airborne route and by respiratory droplets. It is characterized by a pruritic, generalized vesicular rash that occurs in one to six crops, each crop separated by 24 to 36 hours. Fever usually is mild. The most common complication is secondary bacterial pyoderma, and although uncommon, pneumonia and secondary invasive infection caused by *S. pyogenes* can cause significant morbidity. Varicella zoster virus remains latent in sensory ganglia after primary infection but can be reactivated as herpes zoster or "shingles," in which case it is manifested as a vesicular eruption involving one to three sensory dermatomes. If infection is acquired in early pregnancy, varicella embryopathy (limb bands or amputation) has been noted in a small fraction of children.

Live, attenuated varicella vaccine became available for universal use in the United States in children between 12 and 18 months of age in

1995. The availability of this vaccine altered the epidemiology of varicella in the United States dramatically. The vaccine has been demonstrated to be highly effective during most outbreaks of varicella in child care^{70,159} and in clinical practice.²⁸² The general effectiveness of the vaccine is 83% to 86% against all forms of the disease and 97% to 100% against moderate to severe disease. However, through active surveillance, breakthrough disease in children who had received one dose of varicella disease was reported. Outbreaks were reported in elementary schools with high rates of vaccine coverage^{52,277} and in a Connecticut child care center in which 25 children contracted varicella (68% of whom were vaccinated). Disease was milder among vaccinated children.¹¹⁸ These observations led to the recommendation by the Advisory Committee on Immunization Practices in 2006 for a universal two-dose varicella vaccine schedule. The first dose is given when the child is 12 to 15 months of age and a second dose at 4 to 6 years of age.⁵⁵ A retrospective cohort analysis of claims data evaluating trends in hospitalizations related to varicella disease demonstrated an 84% decline of hospitalizations in 2012 compared with 1994 (before licensure of the varicella vaccine), and a 38% decline comparing the one- and two-dose vaccine periods.¹⁸⁸

About 10% to 15% of children may develop a popular or vesicular rash at the site of vaccination 5 to 26 days after receiving the immunization. If this does occur without further spread of rash or systemic symptoms, the child may attend child care with the lesions covered. A child with active chickenpox should be excluded from the child care setting until all lesions are scabbed over and the child is able to participate in activities. A child or staff member with varicella zoster need only be excluded if the rash cannot be covered.¹⁴

Measles

Measles (rubeola) is a highly contagious respiratory infection with a household attack rate of 90%. Infants and children less than 5 years of age are at the highest risk for complications. Measles virus is spread by droplets, hand transmission, and the airborne route. The illness usually is moderate to severe; high fever and prominent respiratory symptoms (cough and coryza) and conjunctivitis are present for several days before onset of the rash. Diarrhea occasionally may be a prominent feature. After the rash erupts, the fever and respiratory symptoms persist for several more days. Pneumonia and encephalitis are complications of measles virus infection; each occurs at an incidence of 1 per 1000 cases.

In the year 2000, endemic measles was determined to be eliminated in the United States.²¹⁵ However, outbreaks continue to be reported each year. In 2014, there were 23 measles outbreaks, totaling 667 cases; the largest involved 383 cases among unvaccinated members of a closed community. In early 2015, a notable outbreak of 136 cases occurred at an amusement park during the holiday season. It is thought that the virus was introduced by a foreign traveler, and molecular testing confirmed it was the same strain as was responsible for an outbreak in the Philippines the previous year.³⁰¹

In 2015, an outbreak was reported in a child care center in Illinois, primarily affecting the most vulnerable: infants who were too young to be immunized.⁶⁹ Twelve of the 15 cases were in infants, aged 3 to 11 months, who attended the same group child care. There were 14 infants in the child care room that were exposed, indicating a high attack rate. One of the early cases was initially diagnosed with Kawasaki disease and was not diagnosed with measles until another infected infant was identified.

Measles is effectively prevented by immunization. Current recommendations are to immunize twice: once when the child is between 12 and 15 months of age, and again at 4 to 6 years of age. For exposed, susceptible children, vaccination is recommended with the mumps, measles, and rubella (MMR) vaccine within 72 hours of exposure. During an outbreak, vaccine may be given to children 6 to 11 months of age. However, a child who receives measles vaccine before 1 year of age must still receive the vaccine at 12 to 15 months of age; the first is not counted toward the two required for full protection. Immune globulin can be given within 6 days to an exposed, susceptible individual for whom the live viral vaccine is contraindicated or in whom exposure was more than 72 hours before medical evaluation. This includes infants younger than 12 months and immunocompromised individuals.¹⁵ Children with measles and any exposed unimmunized children should be excluded

from the group care setting until at least 2 weeks after the onset of rash in the last case of measles.

Rubella

Rubella, another exanthematous disease of childhood, is much milder than rubeola but attacks a similar age group. Incidence of rubella in the United States dramatically decreased with universal immunization. Endemic rubella was determined to be eliminated from the Americas in 2009.^{24,180}

Rubella is a highly contagious RNA virus that is transmitted by the respiratory route. Clinically it is characterized by mild fever, lymphadenopathy (postauricular and occipital), and rash. The illness is difficult to distinguish from other viral exanthems. Up to 50% of infections may be asymptomatic.

If rubella is contracted during the first or early second trimester of pregnancy, a severe fetal infection resulting in microcephaly, deafness, congenital heart defects, eye disorders, and psychomotor retardation may result. Acquisition of infection during pregnancy may be a potential hazard for child care personnel or mothers of children who attend child care if an outbreak of rubella occurs in the child care setting. In a large outbreak of rubella in Nebraska in 1999, 14 children (nine of whom were <12 months old) and 2 parents acquired their infection in a child care center.⁸⁴

The incidence of congenital rubella syndrome can be minimized by appropriate immunization of preschoolers and personnel. Any child or personnel with noncongenital rubella infection should be excluded from the group child care setting until 7 days after the onset of rash. In outbreak situations, any exposed, unimmunized, or underimmunized children should be excluded from a group setting until they are immunized, or excluded for 21 days after rash onset of the last outbreak case. Children with congenital rubella syndrome may shed virus in urine or nasopharyngeal secretions and be considered contagious until at least 1 year of age. They can be declared noncontagious if two cultures of clinical specimens obtained 1 month apart are negative for rubella virus after 3 months.¹⁵

Pertussis

Pertussis, or whooping cough, is a highly communicable respiratory disease caused by *Bordetella pertussis*. The attack rate and severity of disease are highest in the first year of life. The illness classically is divided into three phases: catarrhal, paroxysmal, and convalescent. In the first stage, the child has no fever but has symptoms, primarily rhinorrhea, and a cough. When the nasal symptoms resolve, however, the cough becomes and remains very prominent for many weeks. The cough is characterized by paroxysms that are followed by an inspiratory effort (whoop) or leave the child exhausted and occasionally apneic. Individuals are most infectious during the catarrhal phase and the first 2 weeks of cough. The convalescent stage is the many weeks necessary for complete recovery. Infected children younger than 1 month are at greatest risk for significant morbidity and mortality. Treatment with a macrolide is effective in decreasing the shedding of organisms, and prompt treatment will shorten the course of the disease.

Complete immunization with a five-dose series of acellular pertussis vaccine is effective in preventing most cases of pertussis, although illness does occur in partially and occasionally in fully immunized children.⁶⁸ Pertussis continues to cause disease in vaccinated and unvaccinated persons, with peaks in incidence occurring every few years. In 2012, a pertussis epidemic occurred in the State of Washington, with highest incidence among infants younger than 1 year and children 10 to 14 years of age.⁶⁰ Similar age trends were seen nationwide in the many geographic areas affected by the epidemic. There were 48,277 cases of pertussis reported that year, the highest number since 1955. After a person has been exposed to a case, macrolides provide effective prophylaxis and are the first-line drugs. Trimethoprim-sulfamethoxazole is an alternate in a person who is older than 2 months and unable to tolerate a macrolide, or who has documented macrolide-resistant pertussis.

Prophylaxis is recommended for exposure in child care. If appropriate, booster doses of acellular diphtheria-tetanus-pertussis vaccine should be given to exposed children in a child care or household setting. A

child who has pertussis or has been exposed to a case of pertussis and has symptoms should be excluded from group child care until receipt of 5 days of an appropriate course of a macrolide (azithromycin or erythromycin).¹⁴ If no treatment is received, then exclusion is for 21 days after onset of cough. Immunization status should be updated if a person is underimmunized. Adolescents who have received their primary series of tetanus-diphtheria-pertussis should receive a single dose of the tetanus-diphtheria (Tdap) vaccine at age 11 or 12 years. It is recommended that individuals who are in contact with children younger than 12 months also receive a pertussis booster with the Tdap vaccine. Women should receive Tdap vaccine with each pregnancy regardless of previous vaccination status.¹⁵

Poliomyelitis

Through the Global Polio Eradication Initiative, polio is on the verge of being eradicated worldwide with major vaccination efforts of multiple organizations. Only 73 cases from two countries were reported in 2015.^{104,199} Poliovirus is an enterovirus. Although most infections with this virus are subclinical, in the preimmunization era, polio was the major cause of acquired paralytic disease, especially in older children and young adults. In some developing countries, it was a major health problem until very recently.

Poliomyelitis is prevented effectively by use of either the live oral poliovirus vaccine or the inactivated, enhanced-potency parenteral vaccine (IPV).²²⁵ The Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (CDC) and the AAP recommend a four-dose all-IPV vaccine schedule for routine immunization of all infants and children in the United States.

Mumps

Mumps is a relatively benign infection of childhood that often is asymptomatic. The most prominent clinical feature is parotitis. Occasionally, a clinically significant central nervous system infection causes unilateral sensorineural deafness. This infection had been dramatically reduced by widespread use of the MMR vaccine. However, large outbreaks continue to occur in the United States. In 2006, there was an outbreak primarily among vaccinated young adults in the Midwest,⁸⁶ and in 2009, an outbreak occurred primarily among vaccinated school-aged children in a religious community in New York and New Jersey.^{28,56}

There was a dramatic increase in numbers of cases in 2012–2014, with the CDC reporting 1057 cases in 2015 and 1661 cases in the first half of 2016. Since the early 2000s the age of highest incidence of mumps has shifted from the preschool child to adolescents and young adults. This is possibly a result of waning immunity. Children with mumps should be excluded from the group child care setting until 5 days after the onset of parotid swelling.

Rotavirus

Before the introduction of rotavirus vaccine for the immunization of infants in 2006, rotavirus was the most common identifiable infectious cause of gastroenteritis leading to hospitalization in young children, and accounting for more than 25% of diarrheal cases in the United States.^{40,89,149,198,286} It is currently a significant cause of diarrhea in developing countries, contributing substantially to the worldwide mortality figures for gastroenteritis.

A very low inoculum of rotavirus is needed to cause infection. The virus can be recovered from asymptomatic hosts, especially neonates and infants.⁶⁶ It is shed in large numbers in the stool of patients with symptoms, thereby contributing to the high prevalence of the virus on environmental surfaces during outbreaks.²⁹¹ Viral shedding occurs both before and after symptoms have appeared.²²² Most illnesses caused by rotavirus occur in the cooler months in temperate climates but occur year-round in tropical areas. The peak attack rate is in the 6- to 24-month-old age group. Before the introduction of vaccine, many outbreaks were reported in group child care settings.^{31,213,222,231} In prospective studies of diarrheal illness in children attending child care, rotavirus was implicated in 6% to 24% of cases of gastroenteritis,^{31,30,149,266} as well as in 20% to 40% of outbreaks.³¹

In early 2006, a bovine rotavirus-based pentavalent vaccine was licensed for use in US infants. Three doses of the vaccine are given

orally at 2, 4, and 6 months of age.¹⁷ In 2008, a monovalent attenuated human rotavirus was licensed for a two-dose schedule given orally at 2 and 4 months.

Both have been shown to be effective against rotavirus of any severity.^{41,47,75,90,187,256} A review of a claims database for one health care system (2008–11) demonstrated much lower rates of hospitalizations and emergency department visits coded for unspecified gastroenteritis and rotavirus among households in which an infant had been vaccinated against rotavirus, thus demonstrating indirect protection among household members.⁷⁴

Treatment of children with rotavirus diarrhea is supportive. Exclusion criteria from child care are the same as those for any diarrheal illness. Children should be excluded if the stool cannot be contained in the diaper or accidents occur in toilet-trained children. Return to child care is appropriate when the stool is controlled and the child's illness does not put extra burden on child care staff.

Hepatitis A Virus

Before the institution of universal immunization of young children, HAV, an enterovirus, was a common cause of acute hepatitis in children. As with other enteric pathogens, this organism is transmitted by the fecal-oral route. Manifestations of infection vary remarkably according to age. In young children (<6 years), infection with HAV may be entirely asymptomatic or associated with relatively mild and nonspecific symptoms such as low-grade fever, anorexia, nausea, vomiting, and diarrhea in 30% of patients. Jaundice, a more specific marker of liver disease, occurs in fewer than 10% of children younger than 6 years.¹²³ In contrast, adults with hepatitis A often are icteric in conjunction with other gastrointestinal symptoms. Infection, when symptomatic, usually lasts several weeks but occasionally can become protracted.

Transmission is primarily by person-to-person spread, but fomites may play an important role because the organism can persist and remain infective in the dried state for months.²⁰⁰ HAV is shed in high density in the stool of infected persons from 2 weeks before until 1 week after the onset of clinical symptoms.

Intramuscular immunoglobulin given within 2 weeks of exposure to susceptible individuals (infants <12 months of age) is very effective in preventing symptomatic disease. Unimmunized children older than 12 months can be vaccinated as postexposure prophylaxis.¹⁵ Since the recommendation for universal vaccination of children 12 to 23 months of age, there has been a significant reduction in the incidence of acute HAV disease.⁵⁴ Clusters of infection have been reported among close contacts of asymptomatic, newly arrived international adoptees from countries with high rates of HAV.¹⁰⁹ The AAP, Advisory Committee on Immunization Practices (ACIP), and CDC recommend vaccination of close contacts of internationally adopted children at risk for HAV, including parents and babysitters.¹⁸

HAV vaccine is recommended for children beginning at age 12 months. If a person in the child care setting does contract HAV, or there are two or more households affected by HAV, unimmunized child care contacts should receive HAV vaccine or intravenous immune globulin. Children and adults (especially food handlers) with HAV disease should be excluded from the group child care setting until 1 week after the onset of illness or after they are cleared by public health officials.¹⁵

Hepatitis B Virus

HBV is a DNA-containing virus that causes infections with a wide range of clinical manifestations from asymptomatic seroconversion to fatal hepatitis. Infection is more likely to be asymptomatic in children than in adults.²⁰² Common symptoms include fever, fatigue, anorexia, malaise, and jaundice. Other gastrointestinal symptoms, such as nausea, vomiting, and diarrhea, may be prominent. Joint symptoms (arthritis and arthralgias) and cutaneous lesions (papular acrodermatitis) may be noted early in the course of the illness.

The most common modes of transmission of HBV in adults are contact with blood and sexual activity. Young children usually acquire infection with HBV by vertical transmission from their mother at delivery. The maternal infection may be acute or chronic. Infection acquired vertically by an infant usually is asymptomatic, but it leads to chronic carriage of hepatitis B surface antigen in most cases. With increasing

immigration and adoption of infants from HBV-endemic areas, more HBV-carrier children will be identified.¹⁴¹ It is important to screen children from areas where the prevalence of hepatitis B is more than 2% as they arrive to the United States.

Transmission of HBV within the child care setting is rare but has been reported.^{85,92,247} In one US case, the probable source was a bite by a child who was a carrier of HBV.²⁴⁷ In the other, a child care worker with chapped hands was exposed to the blood of a child who was an HBV carrier.⁹² The third involved an aggressive 21-month-old child with weeping dermatitis and a history of biting other children. Other investigations failed to demonstrate transmission in child care facilities despite long-term contact, including one situation with a high potential for blood exposure.²⁴⁶

Implementation of the current recommendation to screen all pregnant women for HBV and to undertake universal immunization against hepatitis B in infancy is the most effective way to prevent the spread of this infection. Infants born to mothers positive for hepatitis B surface antigen are recommended to receive hepatitis B immune globulin in addition to the vaccine.

Because of the low risk for transmission within the group child care setting, the AAP, American Public Health Association, and CDC do not recommend exclusion of HBV-infected children from child care or HBV screening of children as a criterion for entry. A child known to have active HBV should be excluded from child care if they have weeping sores that cannot be covered, generalized dermatitis, a bleeding problem, or aggressive behavior (e.g., biting or scratching) that may draw blood of the person with HBV. Child care personnel should use Standard Precautions and gloves, handling all blood and body fluids as if they are potentially infected.¹⁵

Animal and Human Bites

249

Morven S. Edwards

Many children delight in teasing dogs, and without caution go too near them, by which they get miserably torn and mangled. ... What these boys had been doing to enrage the dog we cannot tell, but suspect they had been tormenting him in some way, thinking that as he was chained he could not injure them. But they were mistaken in this, and one of them is likely to be bitten very severely.⁷

Anonymous, 1830

HISTORICAL ASPECTS

The consequences of bites resulting from provoking dogs were of concern in the 19th century just as they are today. In early reports, infected bite wounds were noted to contain fusiform bacilli and spirochetal organisms. We now know that the many aerobic and anaerobic organisms composing the normal flora of an animal's mouth are potential bite wound pathogens. Human bites, recorded since the biblical era, are the most

frequent type of bite after dog and cat bites. Reports of infection occurring after human bites in children have been noted in the United States since at least 1910.⁵²

The importance of debridement and drainage in treatment of infected bite wounds was understood in the preantibiotic era, but these infections carried a high morbidity rate. In a report from 1936, amputation was required in one-third of cases in which treatment was delayed for 24 hours or longer.⁹² Adjuncts to cleansing, such as electrocauterization and even radiation therapy, were used in efforts to prevent or to treat infection, but not until the introduction of penicillin was the outcome of bite wound infections improved over that achieved by symptomatic therapy alone.

EPIDEMIOLOGY

More than 150 million cats and dogs are kept as pets in the United States.⁷² The estimated annual incidence is 1 to 2 million dog bites, 400,000 cat bites, 250,000 human bites, and 45,000 snake bites.³⁷ Rabbits, skunks, squirrels, horses, rats, hogs, and monkeys cause at least 1% of bite injuries. Pet ferret attacks have caused severe facial injuries.²⁷ Taken together, bites from nondomestic animals, generally thought to pose a higher risk for transmission of rabies, constitute less than 1% of reported bite wounds. The right arm is bitten most frequently, presumably because of defensive attempts by victims using their dominant arm. At least three-fourths of bites are located on extremities. Facial bites represent only 10% of the total, but two-thirds of them are sustained by children younger than 10 years.

Children are the most common victims of animal bites. More than one-half of all dog bites occur in persons younger than 20 years of age with a peak incidence in children 5 to 9 years of age.⁷⁸ Costs attributable to dog bites exceed \$1 billion per year in the United States.⁷³ Many bites do not require medical intervention and are not reported. Up to 1% of all pediatric emergency department visits during the summer months are for treatment of animal bites.²² Five percent of children seeking care for a dog bite require hospital admission.²⁰ Most bites occur in late afternoon and early evening hours. Boys sustain dog bites twice as often as girls, but girls are bitten more frequently by cats.

Large dogs account for most animal bites and are implicated in most bites with a fatal outcome. Ten to 20 fatal human attacks occur yearly in the United States. At least 25 breeds of dogs were cited in 238 fatalities from dog bites during the past 25 years.⁸² The most common breed is the pit bull, which accounted for 39% of wounds in one series of 650 pediatric dog bite injuries.³⁵ The severity of wounds inflicted by pit bull breeds is due to their biting force and their tendency to inflict multiple bites and to bite and grind their molars into tissue. In most instances (53%), the dog inflicting a bite belongs to the child's immediate or extended family. Stray dogs account for only 10% of bites inflicted. When the circumstances are known, most mammalian bites are provoked, although the victim may not have agitated an animal intentionally.

Infection is a common complication of animal bites. Between 10% and 20% of dog bites and as many as 50% of cat bites for which medical care is sought become infected.⁵⁵ With the exception of monkey bites, which have a high infection rate, infection seldom develops after bites by other mammals. Factors influencing the risk for development of infection include the patient's age, type and location of the wound, and length of time that transpires between the bite and initiation of treatment. Wounds of the hand are more likely to become infected than are those of the arm, leg, or face. Puncture wounds become infected more often than lacerations, superficial wounds, or wounds with skin and soft tissue defects. Infection is likely to develop when wounds are repaired surgically or when care is delayed more than 24 hours after injury.

The incidence of infection after human bites is approximately 10% to 30%. In children, human bites are typically superficial, and the infection rate is low (~10%). Human bites have a peak incidence in the spring and early summer and on Saturdays, especially for the adolescent age group. Alcohol and drug use may play a role. Bites occur more commonly in males than in females, except for the 15- to 20-year-old age groups, in which females are bitten more frequently. Most bites in teenagers are associated with aggressive behavior. Among 322 children who suffered

human bites, 21% were younger than 5 years, 21% were 5 to 10 years, and 58% were older than 10 years.⁶⁵

Biting is a common occurrence in the out-of-home care setting. The incidence peaks in midmorning and during the early school year in September. Toddlers are bitten more often than infants and other preschoolers, and boys are bitten more often than girls.⁸⁶ Approximately 50% of all children enrolled in out-of-home care suffer bite wounds. Most of these bites are minor and do not break the skin. A higher proportion of bites in younger children (such as preschoolers) are to the face, whereas most bites in adolescents are on the upper extremities and hands.

Bites as a sign of child abuse are noted more commonly in the 0- to 4-year-old age group; the age of the abusing parents is usually younger than 20 years for mothers and younger than 22 years for fathers. An attempt should be made to identify the biter and measure distances between circular bite marks to ascertain the spread. In addition, biting children may have learned this behavior from abusive adults and may themselves be victims of human bites.

MICROBIOLOGY

The oral flora of the biting animal, rather than skin flora of the victim, is the source of most isolates from bite wounds, but both can be sources for infection.¹ Infections usually are polymicrobial and contain mixed aerobic-anaerobic isolates. Table 249.1 lists bacterial isolates from the wounds of 50 patients with dog bites and 57 with cat bites that were infected at presentation to an emergency department for care.⁸⁸ A median of five bacterial isolates were found per culture. Slightly more than one-half of the wounds yielded both aerobes and anaerobes, and

TABLE 249.1 Bacteria Isolated From 50 Infected Dog Bites and 57 Infected Cat Bites		
Bacteria	NO. OF PATIENTS (%)	
	Dog Bite	Cat Bite
Aerobes

Others	1 (2)	5 (9)

Modified from Talan DA, Citron DM, Abrahamia FM, et al. Bacteriologic analysis of infected dog and cat bites. *N Engl J Med*. 1999;340:85-92.

anaerobes alone were isolated from slightly more than one-third of the wounds. *Pasteurella* spp. were the most common pathogen in dog and cat bites (50% and 75%, respectively), with *Pasteurella canis* being isolated most often from dog bites and *Pasteurella multocida* subspecies *multocida* and *septica* isolated most often from cat bites. *Pasteurella* carrier rates are as high as 66% for dogs and 90% for cats, so it is not surprising that this organism is associated so commonly with infected bite wounds. Infection has occurred as a consequence of bites by large cats, including lions,¹⁵ cougars,⁵⁶ and tigers,¹⁷ as well as house cats. The type of wound commonly inflicted (i.e., puncture by cats versus laceration by dogs) might explain the species-specific disparity in infection rates.

Other aerobic agents commonly isolated from infected dog or cat bites include streptococci, staphylococci, *Moraxella*, *Neisseria*, and corynebacteria. Although streptococci often are β -hemolytic, *Streptococcus pyogenes* was isolated from only 12% of dog bites and from none of the infected cat bites in one large series.⁸⁸ *Staphylococcus aureus* was isolated frequently from infected dog bites but infrequently from cat bite wounds. Species such as *Capnocytophaga canimorsus* and *Neisseria weaveri* are notable because infections in association with these species have occurred in splenectomized persons and in those with immunocompromising conditions.^{5,60} *Neisseria animaloris* and *Neisseria zoodegmatis* are newly recognized as causes of animal bite wound infections.⁵⁰ Animal bites are implicated as a vehicle for transmission of a number of systemic infectious diseases caused by viruses, fungi, and mycobacteria in addition to bacteria (Box 249.1).⁷⁷ Macaque monkeys kept as pets can transmit herpes B virus.² Transmission of such unusual pathogens as orf virus, *Pseudallescheria boydii*, or *Mycobacterium chelonae* by bites of a goat, dog, or ferret, respectively, has been described.^{53,61,80} Cats can transmit such unusual infections as diphtheria, coccidioidomycosis, and tularemia.^{11,33,91} Tularemia can also be transmitted by the bite of

such diverse species as wild boar, coyote, hog, lamb, muskrat, opossum, raccoon, rat, skunk, squirrel, snapping turtle, and weasel.^{16,66}

The bacteriology of human bite wounds also reflects the human oral flora of the biter. Human saliva and dental plaque can contain more than 42 different species of bacteria in concentrations of 10^9 colony-forming units per milliliter. Table 249.2 lists common human bite wound isolates and their relative frequency of isolation.^{10,14,44,71,87} α -Hemolytic streptococci, especially *Streptococcus anginosus*, are the most frequent isolates. Other common bacterial isolates include *S. pyogenes*, *S. aureus*, *Haemophilus* spp., *Eikenella corrodens*, and oral anaerobes, especially *Fusobacterium*, *Prevotella*, *Veillonella*, and *Peptostreptococcus* spp. *E. corrodens* produces a small colony that “pits” or “corrodes” the agar surface and has a light yellow pigment and an odor like that of hypochlorite bleach.

BOX 249.1 Diseases Transmitted by Animal Bite Wounds

Blastomycosis	<i>Mycobacterium chelonae</i>
Brucellosis	<i>Mycobacterium marinum</i>
Cat-scratch disease	<i>Mycobacterium fortuitum</i>
Coccidioidomycosis	Orf
Diphtheria	Plague
Hemorrhagic fever	Rabies
Herpes B virus	Rat-bite fever ^a
Leptospirosis	Sporotrichosis
Monkeypox	Tularemia

^aBoth infections caused by *Streptobacillus moniliformis* and *Spirillum minus*.

Mycotic aneurysm	Tenosynovitis
Orbital cellulitis	

FIG. 249.1 Dog bite wound–associated tenosynovitis in a 4-year-old girl. *Enterococcus* was isolated from the wound culture.

Cultures of virtually all infected bite wounds grow bacterial pathogens; wound cultures of patients who initially are seen less than 8 hours after incurring an injury, before the development of clinical infection, yield potential pathogens in 85% of cases.³⁸ The bacteriology of early-treated, colonized wounds is remarkably similar to the bacteria isolated from wounds evaluated later with established infection. The average bite wound yields between 3.4 and 5.4 bacterial isolates, including 1.7 to 2.4 aerobes and 1.7 to 3 anaerobes. Anaerobes are isolated from more than 50% of human bite wounds, almost always in mixed culture with aerobes, and they are associated more often with more serious infections, amputation, and the presence of abscesses.⁸⁷ Many of the anaerobes isolated from human bite wounds, especially *Prevotella* and *Porphyromonas* spp., are β -lactamase producers.

In addition to oral bacterial infection, human bites have been associated with viral infections, such as those caused by herpes simplex virus,⁶⁸ cytomegalovirus,⁶⁸ hepatitis B virus,⁵¹ hepatitis C virus,²⁶ and possibly human immunodeficiency virus (HIV),⁶ as well as syphilis,²⁸ tuberculosis,³⁸ actinomycosis,¹² and tetanus⁷⁰ (Box 249.2).

CLINICAL MANIFESTATIONS

Signs of infection after animal bites develop within hours to several days after injury. Infection is the usual reason that patients seek medical attention more than 8 to 12 hours after injury, whereas those seen earlier are more concerned with prophylaxis or surgical repair. Findings suggestive of wound infection include localized swelling, erythema, and pain with or without serosanguineous or purulent drainage (Fig. 249.1). The clinical findings vary with the infecting organism, site of injury, and type of bite. The jaws and teeth of dogs are likely to produce multiple puncture wounds as well as jagged lacerations with devitalized tissue. These lesions can be associated with depressed skull fractures, sometimes in more than one cranial region. Puncture wounds, particularly those inflicted by cat bites, often are deceptively innocuous. Inoculation

of organisms deep into poorly vascularized areas, such as tendon sheaths, fascia, joints, and bones, is likely to result in an infected wound.

The characteristic findings of *P. multocida* infection include a rapid onset of intense pain, swelling, and erythema, often within hours after injury. Cellulitis is usually evident within 24 to 36 hours after the bite. Despite these intense local symptoms, patients generally are afebrile, and less than 20% have lymphangitis and regional adenitis. Patients with wound infection caused by staphylococci or streptococci usually experience less intense pain, have a delay between injury and the onset of symptoms of days rather than hours, and may have a more diffuse, less fiery cellulitis. Gas in tissues of the forearm clinically suggestive of clostridial gas gangrene has occurred in infections caused by *S. anginosus* and *Streptococcus mutans* after horse bite lacerations.⁶⁷ Wound infection clinically resembling that caused by *P. multocida* from which the related but more unusual gram-negative rod *Actinobacillus lignieresii* was isolated has been reported in a child who sustained a facial bite by a horse.²¹

Some of the complications resulting from direct extension or generalized spread of infection caused by animal bites are summarized in Box 249.3. Tenosynovitis caused by *P. multocida* can be apparent within hours or can manifest days to weeks after injury, when persistence of swelling, tenderness, or pain and a mass overlying the involved tendon sheath suggest the diagnosis. *Pasteurella* osteomyelitis that develops after a cat bite is characterized by pain, swelling, and tenderness over the involved bone.⁵⁴ When the periosteum has been entered, osteomyelitis can develop despite early administration of local and antibiotic treatment. Bites to the cranium occur with relative frequency in small children because their heads are at the level of the mouth of medium- to large-sized dogs. Complications of perforating cranial bites in children include compound depressed skull fractures, brain abscess, dural lacerations, and extensive intracerebral injuries, which can prove fatal.^{3,15} Brain abscess and meningitis can occur as complications of these injuries.

In patients with systemic infections transmitted by animal bites, the incubation periods and clinical manifestations vary with the causative agent. For example, streptobacillary rat-bite fever occurs after an incubation period of less than 1 week, whereas spirillary rat-bite fever, or sodoku, has a 2-week asymptomatic interval after the bite. For many of the infections listed in Box 249.1, the bite wound serves as the site of inoculation and has healed completely during the incubation period.^{36,62,83} For example, fatal encephalitis has resulted from the bite or scratch of a monkey that is actively shedding herpes B virus. Post-exposure prophylaxis with an antiviral such as acyclovir can prevent life-threatening illness.² Isolation of *C. canimorsus* is common among patients with splenectomy, alcoholism, and chronic lung disease.⁷⁶ The symptoms heralding the onset of systemic infections caused by animal bites are discussed in their respective chapters.

A high index of suspicion can be required to trace the infection to the animal source. For example, most cases of human plague in the United States result from bites by infected fleas, but contact with a domestic cat infected with *Yersinia pestis* can be the source of infection.³² With tularemia, an ulcerative or pustular lesion develops at the bite site 4 to 7 days after injury and is associated with fever, chills, and painful regional adenopathy. In a case of *Mycobacterium marinum* infection that developed after a dolphin bite, one of several discrete fluctuant masses containing the isolate developed in an area just proximal to the original wound.³⁰ *Mycoplasma* has been implicated in “seal finger” from

BOX 249.4 Potential Complications of Human Bite Wounds

Abscess	Scarlet fever
Cellulitis	Septic arthritis
Compartment syndrome	Sepsis
Fracture	Tendon severance or injury
Necrotizing fasciitis	Tenosynovitis
Nerve severance or injury	Toxic shock syndrome
Osteomyelitis	

a seal skin, tooth, or claw injury, an infection characterized by severe pain and massive swelling and erythema 4 to 8 days after injury.⁹ With cat-scratch disease caused by *Bartonella henselae*, a papule or pustule may be present at the original bite site when systemic signs develop. An ulceration at the site of a rodent bite has been described with sporotrichosis.⁴⁹

Human bites can be categorized as those resulting in paronychia infection, occlusional bites, and clenched-fist injuries. Potential complications of human bites are noted in [Box 249.4](#). Paronychia is an infection of the structures of the distal phalanx, either those surrounding the nail or the bone itself. The area is red, tender, and swollen and may have associated purulence.

Most occlusional wounds are minor and require routine care with cleansing and bandaging. The infection rate after occlusional bite wounds is 10% to 30%, and 87% of these may require hospitalization.⁸ Wounds to the hand and with any edema or crush injury and those that involve a bone or a joint have a greater potential to become infected. Infections usually present as cellulitis. With early treatment, these injuries rarely result in serious complications. The infection generally spreads proximally, and fewer than 5% of cases have associated fever, lymphangitis, or lymphadenopathy. A malodorous discharge or abscess can be present if anaerobes are involved. Complications may be limited to skin defects when skin avulsion has occurred, but septic arthritis and osteomyelitis may develop if the joint or bone is involved.⁴⁵ In immunocompromised hosts, such as those with hematologic malignant disease or neutropenia, sepsis may occur. Amputation can be necessary as a result of the initial bite or as a consequence of chronic infection.⁶³ Tendon injury, primary nerve injury and tenosynovitis, compartment syndrome, and resultant secondary nerve damage can occur.

Clenched-fist injuries, or “fight bites,” are the most serious of human bite wounds and occur when the closed fist of one person strikes another in the teeth and a break in the skin occurs.⁴⁷ The most common cause is a fight, although the injury can occur during contact sports. The metacarpophalangeal joint of the middle finger of the dominant hand is most often involved. The break in the skin may be only 2 to 5 mm in length but often results in penetration into the joint or even into bone. Patients and physicians may underestimate the potentially serious nature of these wounds. Bacteria penetrate the knuckle area during the initial contact and, on relaxation of the hand, are carried by the tendons proximally into the potential spaces of the hand. Infection can spread laterally, between the collateral and accessory ligaments, or dorsally into the thin-walled bursa overlying the metacarpal head or into the palmar deep spaces of the hand. The swelling usually spreads proximally from the site of injury. Patients often avoid seeking attention initially because of the circumstances surrounding the injury and 6 to 8 hours later seek medical attention with a painful, throbbing, swollen, infected hand. Purulent exudate can be foul smelling if anaerobes are present.

The range of motion of the hand usually is limited by swelling and edema but also can be limited as a result of tendon or nerve injury or severance. Osteomyelitis of the small bones of the hand can present as continued pain, swelling, and erythema with or without drainage 10 days to 3 weeks after the injury has occurred. Osteomyelitis and septic arthritis caused by *E. corrodens*, often in association with α -hemolytic streptococci, frequently are insidious and persistent and may lead to amputation, especially if treated with the wrong antibiotics. Permanent limitation of range of motion and joint stiffness can occur.

DIAGNOSIS AND TREATMENT

The most important aid to establishing the diagnosis of infection after bite wounds is the proper use of wound cultures. A culture specimen need not be obtained from children evaluated in the immediate postinjury period (the first 12 hours) unless the bite is located on the face or hand or signs of infection are present. Isolates from an uninfected but contaminated wound do not predict the future development of infection. Routine determination of the microorganisms colonizing bites on the face or hands is useful because of the potentially devastating consequences of infection at these locations. After the wound has been cleansed, culture should be performed routinely when evaluation is at an interval exceeding 12 hours from the time of injury, except for wounds evaluated more than 24 hours after injury with no signs of infection.

When material is obtained for wound culture, the microbiology laboratory should be informed that the source of the specimen is a bite wound. This information should optimize accuracy because *P. multocida* can be mistaken morphologically for *Neisseria* or *Haemophilus influenzae*. Appropriate media must be used for the isolation of anaerobes, and gram-negative rods should be considered pathogens. A blood culture should be performed if fever or systemic toxicity is evident, although bacteremia occurs rarely. Diagnostic imaging is indicated when the periosteum has potentially been penetrated. Magnetic resonance imaging or computed tomographic imaging can detect periosteal defects, particularly in children with cranial bite wounds. For patients in whom wound infection has extended locally, sutures, if present, should be removed and material from the involved tissue obtained for study. Material should be aspirated from areas of cellulitis and drained from areas of frank abscess formation. If osteomyelitis is suspected, a bone biopsy should be submitted for Gram stain, culture, and histopathologic evaluation. If the course of the wound infection is indolent, acid-fast stains and mycobacterial cultures should be performed. Serum for serologic testing should be obtained from patients with symptoms suggesting a systemic infection. The details of the indicated diagnostic evaluation for systemic infections transmissible by animal and human bites are specified in the appropriate chapters.

The basic elements of management are outlined in [Box 249.5](#). The wound should be cleansed with clean water or saline, and any foreign body or debris and necrotic tissue should be removed. Cautious debridement is indicated for some wounds, with care being taken to not create a potential skin defect. The wound should be irrigated, with a large syringe and needle or catheter tip used as a moderate-pressure jet to diminish the bacterial inoculum. Puncture wounds should be cleansed but not irrigated because irrigation may damage tissues further.

The value and risks associated with primary closure remain controversial. Data support surgical closure with interrupted sutures or adhesive strips for patients with wounds less than 12 hours old and without any signs of infection. Early primary closure has also been successful for wounds to the face and neck. The blood supply to the head and face area is superior to that of most other anatomic areas, and these areas are rarely dependent; therefore, edema and swelling resolve more rapidly or do not develop. In one prospective study, primary closure in patients presenting less than 8 hours after injury was associated with only slightly higher development of wound infection than that occurring after non-bite wound lacerations.¹⁸ Most nonpuncture animal bite wounds except those involving the hands or feet can be treated by primary closure without substantially increasing the risk for development of infection.³⁴ Wounds to the hands should be observed and left open for either delayed primary or secondary closure. Infected wounds should not be closed initially, but approximation of margins and closure by either delayed primary or secondary intent is advisable for infected nonfacial wounds.

Some clinicians prefer to approximate wound edges with adhesive strips or tissue adhesive rather than to suture wounds. In cases of clenched-fist injury, a hand surgeon should examine the wound to determine whether the joint capsule or bone has been compromised. Surgical consultation with an appropriate specialist is appropriate for complicated wounds and for most hand wounds. Elevation of a swollen or inflamed part is crucial to healing. The elevation should be maintained above the level of the heart. Legs and hands also can be elevated with pillows.

Definitive data on which to base the use of antibiotic prophylaxis after animal bites are lacking. Prospective clinical trials that have addressed the issue find significantly lower infection rates for prophylaxis of wounds in patients presenting at 9 to 24 hours after injury but not for those presenting less than 9 hours after injury.⁸⁵ Prophylactic dicloxacillin, cephalexin, or erythromycin was not beneficial therapy for low-risk dog bite wounds in another prospective study because infection rates for wounds in both the antibiotic and control groups did not exceed

5%.²² A meta-analysis of eight randomized trials totaling 783 patients with dog bite wounds found that prophylactic antibiotics did reduce the incidence of infection.¹⁹ The estimated cumulative incidence of infection was 16% in controls, and the relative risk was 0.56 (95% confidence interval, 0.38–0.82) in patients given antibiotics. Treatment of approximately 14 patients was required to prevent one infection. Some consider antibiotic use therapeutic rather than prophylactic in this setting and suggest that antibiotic therapy be given in all cases of dog bites except those initially evaluated more than 24 hours after injury with no clinical signs of infection.⁹³

Administration of a 3- to 5-day course of broad-spectrum antimicrobial therapy for children with fresh wounds and those with cat bite wounds may decrease the rate of infection.⁴ Antimicrobial therapy should also be initiated in the following circumstances: wounds with signs of infection; all cat bite wounds; moderate to severe bites, especially if edema or crush injury is present; puncture wounds, particularly if bone, joint, or tendon sheath penetration may have occurred; facial wounds; all hand or foot bite wounds; wounds in the genital area; and wounds in asplenic or immunocompromised persons.^{38,90}

Antimicrobial agents should be selected according to the most likely pathogens and their usual susceptibility patterns to antimicrobial agents.^{39,44} If cultures are performed, therapy should be adjusted according to the organisms isolated and their susceptibility to antimicrobial agents. The activity of antibiotics commonly used against the usual bite wound pathogens is outlined in Table 249.3. Common pathogens to be considered in the selection of antimicrobial therapy include streptococci, *S. aureus*, *Haemophilus* spp., *E. corrodens*, *P. multocida*, and β -lactamase-producing oral anaerobes. Methicillin-resistant staphylococci are relatively common flora in healthy cats but isolation of methicillin-resistant *S. aureus* (MRSA) from infected bite wounds occurs uncommonly.^{72,74}

The oral agent of choice for dog, cat, mammal, and human bites is amoxicillin-clavulanic acid. For penicillin-allergic children, the combination of either an extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole in conjunction with clindamycin can be substituted.⁴ The intravenous agent of choice is ampicillin-sulbactam; piperacillin-tazobactam can be used as an alternative.⁴ For penicillin-allergic children, the combination of either an extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole in conjunction with clindamycin or a carbapenem should be administered.⁴ Consideration should be given, for children with severe bite wound infections, to providing coverage with vancomycin for MRSA while cultures are pending.

First-generation cephalosporins are of limited utility because of poor activity against *E. corrodens*, and some anaerobes and should not be used as empirical monotherapy. Erythromycin also has poor activity against *P. multocida*, *E. corrodens*, and *Fusobacterium nucleatum*, and

BOX 249.5 Management Procedures for Bite Wounds

Obtain history from patient

- Situation leading to injury
- Place of occurrence
- Patient allergies
- Other medications (potential interactions)

Perform evaluation of patient

- Nerve function
- Tendon function
- Vascular integrity
- Range of motion
- Potential bone and joint involvement

Diagram or photograph wound

Mark leading edge of cellulitis

Culture wound (if infected)

Irrigate wound (do not irrigate puncture wounds)

Debride wound cautiously

Obtain diagnostic imaging for penetrating injuries overlying bones or joints, if fracture suspected or foreign body suspected

Drain abscesses

Operative debridement (for removal of devitalized tissue and for severe bites, as indicated)

Administer antimicrobial agents (prophylactic therapy, 3–5 days; longer duration for established infection)

Elevate injured area

Close the wound (see text)

Immobilize wound area (3 days for hands)

Have the patient exercise the injured area (if previously immobilized)

Administer tetanus toxoid

Submit health department report (if required)

TABLE 249.3 Comparative in Vitro Antimicrobial Activity of Selected Oral Antimicrobial Agents Against Common Bite Wound Pathogens

+, Active; —, poorly active or inactive; v, variable.

its use as monotherapy can lead to therapeutic failure. Newer macrolides, including azithromycin, show improved activity compared with erythromycin against the spectrum of bite wound pathogens, but *Haemophilus* spp. and *F. nucleatum* remain relatively resistant.⁴⁴

The quinolones exhibit broad activity against the pathogens implicated in bite wounds.^{42,87} Linezolid has greater activity than the macrolides against the gram-positive organisms and fusobacteria isolated from human bite wounds, but some aerobic gram-negative organisms are at the susceptibility breakpoint.⁴¹ Ceftaroline has excellent activity against *P. multocida* and other *Pasteurella* species and aerobic gram-positive organisms, including MRSA.⁴³ Antimicrobial therapy should be adjusted in accordance with the patient's individual isolates and susceptibility pattern.

If any question exists about the prompt filling of a prescription because of financial or other concerns, a dose of intramuscular or intravenous antibiotics should be administered and hospitalization considered. Patients' wounds should be reexamined within 48 hours. If outpatient therapy is initiated and the cellulitis advances, hospitalization is indicated. Indications for hospitalization also include patient non-compliance and virtually all clenched-fist injuries.

The duration of antimicrobial therapy is determined by the type and severity of infection. Prophylactic antimicrobial agents typically are given for 3 to 5 days. A suggested duration of therapy, assuming that proper drainage has been established for infected wounds, is 10 days for cellulitis or localized abscess, 2 to 3 weeks for tenosynovitis, and 3 to 6 weeks for osteomyelitis. When improvement is evident, treatment can be completed orally. At least 4 weeks of intravenous therapy should be administered to patients with endocarditis. Although the number of patients is too small for the required dosage to be established with certainty, ampicillin (400 mg/kg per day) has been used successfully for the treatment of *P. multocida* meningitis.⁴⁶

In every child sustaining a bite wound, immunization status should be determined to assess the need for tetanus prophylaxis and whether rabies prophylaxis should be undertaken (see the appropriate chapters).

REPTILE BITES

Approximately 4700 people in the United States are bitten yearly by poisonous snakes.⁸⁴ Approximately one-half occur in people younger than 20 years. The curiosity of children can contribute to this exposure because many are bitten while handling poisonous snakes. Boys are more likely than girls to incur snake bites requiring antivenom therapy.⁶⁹ An average of five persons die of snake bites each year.⁵⁸

Venomous snakes are divided into four families, two of which, the Crotalidae (rattlesnakes, copperheads, and water moccasins) and the Elapidae (coral snakes), are found in the United States. Snake venoms are among the most complex of proteins. The local effects of the venom of pit vipers (Crotalidae), which is rich in proteolytic activity, include swelling, pain, edema, ecchymosis, and tissue necrosis with the formation of bullae. Systemic effects result from increased blood vessel permeability and hemolysis and may include hematuria, hematemesis, and disseminated intravascular coagulopathy. The venom of the eastern coral snake causes minimal local tissue destruction. It is a neurotoxin that produces paresthesia of the involved extremity, followed by involvement of the cranial nerves and bulbar paralysis.

Goldstein and associates⁴⁰ isolated 58 aerobic and 28 anaerobic organisms after culturing the venom from 15 rattlesnakes. The aerobes most commonly isolated were *Pseudomonas aeruginosa*, *Proteus* spp., and *Staphylococcus epidermidis*. Among the anaerobes, *Clostridium* spp. were the isolates found most frequently; *Bacteroides fragilis* also was recovered. Defecation of prey during ingestion contributes to this preponderance of gastrointestinal flora. When the fangs are cleansed carefully before collection, the venom itself is sterile, thus indicating that bacterial isolates potentially contaminating snake bite wounds are a reflection of the oral flora.

Alligators are generally not aggressive toward humans.⁵⁹ In persons sustaining alligator bite wounds, infection is caused most commonly by *Aeromonas hydrophila*. A report of mixed infection with *A. hydrophila*, *Enterobacter agglomerans*, and *Citrobacter diversus* and the frequency with which *Proteus vulgaris* and *Pseudomonas* spp. are isolated from alligator mouths suggest that treatment of alligator bites should be

directed at gram-negative species.²⁹ *Vibrio* infection should be suspected in victims of shark bites as well as in all wounds exposed to salt water.⁷⁵ *Aeromonas* spp. and other gram-negative bacilli, as well as *S. aureus* and anaerobes, can infect shark bites.⁷⁹ The exotic pet industry is growing in the United States, and the common green iguana is a popular pet. Few cases of infections from iguana bites have been reported, and most bites do not have serious effects because these creatures are generally nonaggressive, but *Serratia marcescens* cellulitis has been observed.^{31,48} The mouths of Komodo dragons harbor many species of bacteria, including *Escherichia coli*, staphylococci, and streptococci, but Komodo dragon bites to humans are rare.¹³

The inflammatory changes of envenomation can be difficult to differentiate from those of infection. Some experts suggest use of a broad-spectrum antibiotic for injuries with severe tissue involvement but not for bites with minor or minimal envenomation.⁸¹ Others suggest that prophylactic antibiotics are not required in snake bite victims.^{64,89} Amoxicillin-clavulanate is an appropriate oral antimicrobial and ampicillin-sulbactam plus gentamicin is an appropriate parenteral regimen for empirical treatment of reptile bite wounds.⁴ Piperacillin-tazobactam can be used as an alternative to ampicillin-sulbactam. The oral alternatives for penicillin-allergic children are the same as those given for other animal bite wounds. The suggested parenteral regimen for a penicillin-allergic child is clindamycin plus an extended spectrum cephalosporin or gentamicin or aztreonam or quinolone or a carbapenem. Treatment should be guided by the results of cultures and susceptibility testing.

PREVENTION

Bite wounds are, at least in part, preventable injuries. Prevention strategies include appropriate infection control measures in the sports setting and education of young athletes as well as their coaches and trainers. Bites can occur in the out-of-home care setting, even when caregivers are vigilant. A cross-sectional survey of 5- to 15-year-olds found that dog bite prevention knowledge was poor, particularly among younger children.²³ Video-based dog bite prevention interventions are effective in improving short-term knowledge in preschool- and school-aged children.^{24,57} There is as yet no direct evidence that educational programs actually lead to a reduction in dog bite rates in children and adolescents. Educating young children could improve their attitude and behavior toward dogs, and data are needed to evaluate dog bite rates as outcomes of such interventions.²⁵

The intentional delivery of *Bacillus anthracis* spores through mailed letters or packages established the clinical reality of bioterrorism in the United States in the autumn of 2001.^{12,52} An understanding of the epidemiology, clinical manifestations, and management of the more credible biologic agents is critical to limiting morbidity and mortality from a bioterrorism attack.^{20,37,47,59}

Implementation of an effective response to deliberate release of biologic agents by terrorists requires detection and reporting of cases as soon as possible.^{7,16} Prompt recognition of unusual clinical syndromes and increases above seasonal levels in the incidence of common syndromes or deaths from infectious agents is critical to an effective response.^{7,27,47,57}

HISTORY

The concept of biologic warfare or terrorism is not a new one. In 1346, the Tatar force attacking Caffa (also Caffa, now Feodosia, Ukraine) was struck by a plague epidemic.^{17,82} To take advantage of this development, the Tatars catapulted the corpses of their plague victims into Caffa. An outbreak of plague did occur in the city, representing one of the first biologic attacks recorded.^{17,82}

Smallpox first was used as a biologic weapon during the French and Indian War of 1754 to 1767.¹⁷ Apparently, British troops deliberately infected Native Americans with smallpox by giving them blankets from infected patients.

A secret branch of the Japanese army, Unit 731, reportedly caused outbreaks of plague by dropping plague-infected fleas over populated areas of China in World War II.⁴⁵ Bomb experiments of weaponized anthrax spores were conducted by the Allies on uninhabited Gruinard Island near the coast of Scotland and resulted in heavy contamination in 1942.⁶⁹ Viable anthrax spores persisted until the island was decontaminated with formaldehyde and seawater in 1986.

In response to a perceived German biologic warfare threat, the United States began research into the offensive use of biologic agents in 1943 at Camp Detrick (renamed Fort Detrick in 1956) in Frederick, Maryland.¹⁷ President Nixon stopped all offensive biologic and toxin weapon research and production by executive order in 1969. Included among the agents destroyed as a result of this action were *B. anthracis*, botulinum toxin, *Francisella tularensis*, *Coxiella burnetii*, Venezuelan equine encephalitis virus, *Brucella suis*, and staphylococcal enterotoxin B. Begun in 1953, the US defensive program at Fort Detrick continues today as the US Army Medical Research Institute of Infectious Diseases (USAMRIID).¹⁷

The Biological and Toxin Weapons Convention was ratified in 1972 and went into effect in 1975.⁸¹ It prohibits the development, production, stockpiling, or transfer of biologic weapons agents (microbial pathogens and toxins) for other than peaceful purposes and any devices used to deliver these agents. One hundred forty-three states are parties to the convention, with an additional 18 signatories. Unfortunately, the treaty was not accompanied by effective provisions for verification.

Although the Soviet Union signed the convention at its inception in 1972, it formed and funded an organization known most recently as Biopreparat (Chief Directorate for Biological Preparations) 2 years later.²³ This organization was designed to carry out offensive biologic weapons research, development, and production concealed behind legal and civil biotechnology research. Its capacity for production of biologic weapons included plague, tularemia, glanders, brucellosis, anthrax, smallpox, and Venezuelan equine encephalomyelitis.²

An incident at a military microbiology facility in Sverdlovsk (now Yekaterinburg) in the former Soviet Union in 1979 proved to be a grim

warning of the dangers of biologic weapons science.⁶¹ An accidental aerosolized release of anthrax spores resulted in at least 79 cases of anthrax, including 68 deaths. This largest reported outbreak of inhalational anthrax occurred in people living or working within a 4-km zone downwind of the facility.

Iraq's biologic warfare program commenced in earnest in 1985 after initial explorations in the late 1970s.⁸⁴ By the end of the Persian Gulf War in 1991, Iraqi scientists had investigated the biologic warfare potential of five bacterial strains, one fungal strain, five viruses, and four toxins. The United Nations Special Commission suspects that from 1991 to 1995, Iraq actively preserved biologic weapons capability, including botulinum toxin, anthrax, and *Clostridium perfringens* spores.²³

The Japanese cult Aum Shinrikyo made several unsuccessful attempts at disseminating anthrax from rooftops and trucks in central Tokyo in the early 1990s before successfully releasing sarin nerve gas into Tokyo's subways and killing a dozen people in 1995.⁸⁵ A large community outbreak of salmonellosis was caused by the intentional contamination of restaurant salad bars for political reasons by members of a religious commune in The Dalles, Oregon, in 1984.⁷⁶

EPIDEMIOLOGY

Potential biologic weapons share several characteristics. Ease of acquisition and production is a primary consideration. Other ideal properties include the potential to be aerosolized (particle size, 1–10 µm) and dispersed over a wide geographic area as well as resistance to sunlight, desiccation, and heat. The potential to cause lethal or debilitating disease and person-to-person transmission are important features, as is lack of effective therapy or prophylaxis.^{30,37,45}

Any small or large outbreak of disease merits evaluation as a potential biologic event.⁶⁷ Unusually high rates of disease (e.g., a cluster of life-threatening pneumonia cases in previously healthy adults) as well as unusual clinical syndromes should signal a warning. After definitions of the cause and rate of attack have been determined, an epidemic curve based on the number of cases during a specific time can be calculated. The epidemic curve in a biologic event triggered by a point-source exposure most likely would be compressed, with a peak occurring in a matter of hours or days. The occurrence of a second curve peak would be possible with contagious agents as a result of person-to-person transmission. The steep epidemic curve expected in a bioterrorism attack is similar to what would be seen with other point-source exposures, such as food-borne outbreaks.

Several epidemiologic clues may be helpful in determining whether further investigation into an outbreak as a potential biologic attack is warranted. Major indicators are a large epidemic, especially in a discrete population; more severe disease than expected for a given pathogen; and a disease unusual for a given geographic area (e.g., pulmonic tularemia in an urban setting). Multiple simultaneous epidemics of different diseases, outbreaks with both human and zoonotic consequences, and unusual strains or susceptibility profiles are additional helpful parameters. Variable attack rates as a function of agent release relative to the interior or exterior of a building also would be useful.⁶⁷ Although most bioterrorism attacks will be covert,^{7,16} intelligence revealing plans for an attack, terrorist claims of deliberate release, or direct physical evidence of an attack obviously would point to a biologic event.

The emergence of mosquito-borne West Nile virus encephalitis in New York City in the summer of 1999 is an example of a naturally occurring outbreak that had elements of a potential bioterrorist attack.^{7,27,71} This outbreak represented a disease occurring in an unusual (previously nonendemic) area as well as one with zoonotic (birds) in

addition to human consequences. It marked the first documented appearance of West Nile virus in the Western Hemisphere and the first arboviral outbreak in New York City since the yellow fever epidemics of the 19th century.²⁷ A large avian die-off, affecting primarily crows, preceded the outbreak in humans by at least several weeks.

CRITICAL BIOLOGIC AGENTS

In addition to anthrax, critical biologic agents include brucellosis, plague, Q fever, and tularemia; smallpox, viral encephalitis, and viral hemorrhagic fever; and illnesses related to botulinum and staphylococcal enterotoxin B toxins (Box 250.1).^{7,53,57} The five more credible biologic agents are discussed further.

Anthrax

Bacillus anthracis is a large sporulatory, gram-positive rod with three distinct life cycles featuring multiplication of spores in soil, animal (herbivore) infection, and human infection.⁵⁵ Anthrax continues to occur in developing countries where the organism is highly endemic and the use of animal anthrax vaccine is not comprehensive (e.g., Iran, Iraq, Turkey, Pakistan, and sub-Saharan Africa). Human cases may be classified as either agricultural or industrial. Herders, butchers, and slaughterhouse workers in direct contact with infected animals are susceptible to acquiring agricultural infection, and workers in mills that process animal hair and those handling bone meal may acquire industrial infection.⁶⁸

The four forms of human anthrax are cutaneous, inhalational, gastrointestinal, and injectional.³⁵ The most common form is cutaneous, which is acquired through contact with an infected animal or animal products. The much less common inhalational form results from the deposition of spores in the lungs, and gastrointestinal anthrax occurs after the ingestion of infected meat. Because human-to-human transmission of anthrax has not been reported, standard precautions are recommended for hospitalized patients with all forms of anthrax infection.^{46,74}

In the United States, 224 cases of cutaneous anthrax were reported between 1944 and 1994.⁴⁶ Most cases in recent decades were a result of exposure to wool or animal hair.⁶⁸ Cases of cutaneous, inhalational, and gastrointestinal anthrax have been reported in persons who made or handled imported animal-hide drums or participated in drumming events where imported animal-hide drums contaminated with *B. anthracis* spores were used.^{22,33,49}

The clinical features and course of the first 10 confirmed cases of inhalational anthrax associated with bioterrorism in the United States in the fall of 2001 have been reported.⁵² Epidemiologic investigation indicated that the outbreak was a result of intentional delivery of *B. anthracis* spores through mailed letters or packages. The median incubation period was 4 days and ranged from 4 to 6 days. Several clinical features of these patients were not emphasized in earlier reports of inhalational anthrax, a previously rare disease. Drenching sweating, nausea, and vomiting were common manifestations of the initial phase of illness in this outbreak. Pleural effusions were a remarkably consistent clinical feature. No predominant underlying diseases or conditions were noted.

FIG. 250.1 Chest radiograph showing a widened mediastinum secondary to hemorrhagic mediastinitis in a patient with a fatal case of inhalational anthrax. (From LaForce FM, Bumford FH, Feeley JC, et al. Epidemiologic study of a fatal case of inhalation anthrax. *Arch Environ Health*. 1969;18:798-805.)

None of the 10 patients had an initially normal chest radiograph. In addition to characteristic mediastinal widening (Fig. 250.1), paratracheal or hilar fullness, pleural effusions, and parenchymal infiltrates were noted. Computed tomography of the chest was more sensitive than chest radiography in revealing mediastinal lymphadenopathy, and an elevation in the proportion of neutrophils or band forms represented an early diagnostic clue.

Inhalational anthrax previously was reported to be a biphasic illness with influenza-like symptoms such as fever, cough, malaise, fatigue, and chest discomfort in the first phase, followed briefly by 1 to 2 days of improvement before development of the acute phase 2 to 5 days later.¹⁸ However, this brief period of improvement between the initial and fulminant phases of illness was not observed in the first intentional outbreak associated with mail.⁴⁸

The 55% survival rate in these patients was higher than previously reported (<15%). Limited data on treatment of survivors suggest that early treatment with a fluoroquinolone and at least one other active drug (e.g., rifampin, clindamycin, or vancomycin) may improve survival.^{12,74} A systematic review of 82 cases of inhalational anthrax from 1900 to 2005 revealed several findings.⁴¹ Initiation of antibiotic or anthrax antiserum therapy during the prodromal phase of disease was associated with a substantial improvement in short-term survival. In addition, both multidrug antibiotic regimens and pleural fluid drainage were associated with decreased mortality.⁵ Nasal congestion, rhinorrhea, and sore throat, infrequently seen in this series, might help distinguish influenza-like illness from inhalational anthrax.²¹

Newer diagnostic methods for *B. anthracis* infection include polymerase chain reaction assay, immunohistochemistry, and sensitive serologic tests. If meningitis has not been ruled out, the Centers for Disease Control and Prevention (CDC) recommend a regimen including a fluoroquinolone, such as ciprofloxacin; a drug that inhibits protein synthesis, such as linezolid; and a drug that penetrates the central nervous system, such as meropenem. If meningitis has been ruled out with the use of a lumbar puncture, a two-drug regimen that includes a fluoroquinolone plus linezolid or clindamycin is recommended.^{1,10} Corticosteroids should be considered for meningitis or significant mediastinal edema.^{5,48}

Passive immunization with a polyclonal or monoclonal antibody product may offer adjunctive value to antibiotic therapy, especially if

the organisms are resistant to multiple antibiotics.³⁴ Raxibacumab is a human immunoglobulin G1 monoclonal antibody directed against protective antigen, a component of anthrax toxin. A single dose of raxibacumab improved survival in rabbits and monkeys with symptomatic inhalational anthrax.⁶² In trigger-based intervention studies, human anthrax immunoglobulin induced up to 75% survival in rabbits depending on the dose and severity of toxemia at the time of treatment. In nonhuman primates, up to 33% survival was observed in treated animals.⁶³ The CDC recommends antitoxin treatments in cases of systemic anthrax.⁴⁰

Cutaneous anthrax is characterized by a skin lesion evolving from a papule, through a vesicular stage, to a depressed black eschar, often surrounded by significant edema and erythema.^{25,70,74} The lesion, which may mimic a spider bite, is usually painless and located on exposed parts of the body (i.e., face, neck, and arms). The incubation period ranges from 1 to 12 days but commonly is less than 7 days. With effective antimicrobial therapy, fatalities are rare occurrences (<1%). Cutaneous anthrax occurred in a 7-month-old infant who was exposed at his mother's workplace as a result of the fall 2001 attack. This infant displayed severe microangiopathic hemolytic anemia with renal involvement, coagulopathy, and hyponatremia, unusual findings with cutaneous anthrax.³¹ A systematic review of 73 pediatric cases, most of which were cutaneous or gastrointestinal, yielded no striking differences in the presentation of anthrax in children compared with adults.¹¹

Injectional anthrax is characterized by skin lesions similar to those seen in "skin-popping" drug users. Unlike cutaneous anthrax, injectional anthrax is not associated with eschar formation on the skin, and the mortality, even with treatment, is considerably higher, at 34%.⁷⁵

The organism grows readily on sheep blood agar and forms rough, gray-white colonies 4 to 5 mm in size with characteristic comma-shaped or "comet tail" protrusions.⁵⁵ *B. anthracis* is differentiated from other *Bacillus* spp. by an absence of the following: hemolysis, motility, growth on phenylethyl alcohol blood agar, gelatin hydrolysis, and salicin fermentation. Biosafety level 2 conditions for safe specimen processing in the microbiology laboratory and prompt confirmation of suspected isolates at CDC or the USAMRIID in Fort Detrick are warranted.^{46,68}

Postexposure vaccination with an inactivated, cell-free anthrax vaccine is indicated along with ciprofloxacin, doxycycline, or amoxicillin chemoprophylaxis after a proven biologic event has occurred.^{74,79} Recommendations for postexposure prophylaxis (and prolonged therapy after initial therapy for inhalational or cutaneous anthrax) include a 60-day course of antibiotics followed by careful clinical observation. Preexposure vaccination may be indicated for the military and other select populations or for groups for which a calculable risk can be assessed.⁷⁹

Smallpox

After a worldwide eradication program, the last known endemic case of smallpox occurred in Somalia in 1977, and the World Health Organization declared smallpox eradicated in 1980.³⁹ No animal reservoir exists. Current recognized stocks of variola virus are authorized only at the CDC in Atlanta and a Russian state laboratory in Koltsovo. However, additional variola isolates, either long held unreported or acquired through security breaches, also may exist. The World Health Assembly agreed to postpone setting a date for destruction of the world's remaining smallpox virus stocks in May 2014.⁸ The decision on a time line for destruction has been postponed four other times so that crucial research may be completed. Routine vaccination against smallpox ceased in the United States in 1972 and for military personnel in 1990. In December 2002, in response to the possible threat of an intentional release of smallpox virus, the US government implemented a program to immunize select military and public health personnel against smallpox.⁸⁰ Release of an aerosol would be the most likely route of transmission during an act of bioterrorism.

Smallpox is transmitted by respiratory secretions and requires close person-to-person contact. The incubation period generally is 12 to 14 days, with a range of 7 to 17 days. The prodromal illness of classic variola major features an acute onset of malaise, fever, rigors, vomiting, headache, and backache. Two to 3 days later, a discrete rash appears on the face, hands, forearms, and mucous membranes; it spreads to the legs and then centrally to the trunk during the second week of illness.

FIG. 250.2 The lesions of smallpox are at the same stage of development on each area of the body, are deeply embedded in the skin, and are more densely concentrated on the face and extremities. (From Henderson DA. Smallpox: clinical and epidemiologic features. *Emerg Infect Dis.* 1999;5:537-539.)

Lesions progress from macules to papules to pustular vesicles during the course of 1 to 2 days. Umbilicate scabs form 8 to 14 days after onset and leave depressions and depigmented scars.³⁸

In contrast to varicella (chickenpox), the rash of smallpox is centrifugal, with a concentration of lesions on the face and extremities, including the palms and soles, versus the trunk in varicella (Fig. 250.2). Smallpox lesions also are synchronous in stage of development, whereas the lesions of chickenpox appear in crops every few days, which results in lesions at very different stages of maturation in different areas of the skin. Any confirmed case of smallpox represents an international emergency and must be reported to national authorities through local and state health departments.³⁹

Historically, the mortality rate associated with smallpox was 30% for unvaccinated contacts, and currently no antiviral therapy of proven efficacy has been developed. Supplies of vaccinia vaccine and vaccinia immune globulin intravenous (VIGIV) are available only through the CDC.³⁹ Postexposure vaccination and strict quarantine are indicated for all household and other face-to-face contacts of suspected smallpox cases.³⁹

In a limited outbreak with few cases, hospitalized patients should receive care in negative-pressure rooms with high-efficiency particulate air filtration. In addition, precautions using gloves, gowns, and masks are indicated. Home isolation and care are appropriate for most patients in larger outbreaks.³⁹

Between January 24 and October 31, 2003, 37,901 volunteers in 55 jurisdictions received 38,885 smallpox vaccinations through the US Department of Health and Human Services program, with a take rate of 92%.¹⁵ The Vaccine Adverse Event Reporting System (VAERS) received 822 adverse event reports related to these vaccines, an overall reporting rate of 217 per 10,000 vaccinees; 722 nonserious reports to VAERS included multiple signs and symptoms of mild systemic and self-limited local reactions, including fever, rash, pain, and headache.¹⁵

No cases of preventable life-threatening adverse reactions, such as eczema vaccinatum, progressive vaccinia, or fetal vaccinia, were reported. No cases of vaccinia contact transmission occurred. No vaccinee or contact of this program received VIGIV. Rigorous smallpox vaccine safety screening, educational programs, and older vaccinees may have contributed to low rates of preventable life-threatening adverse reactions.¹⁵

Of the adverse events, 100 were designated serious, resulting in 85 hospitalizations, two permanent disabilities, 10 life-threatening illnesses, and three deaths. Among the serious adverse events, 21 cases were classified as myocarditis or pericarditis and 10 as ischemic cardiac events that were not anticipated on historical data. Two cases of generalized vaccinia and one case of postvaccinal encephalitis also were detected.¹⁵

The first confirmed case of eczema vaccinatum in the United States related to smallpox vaccination since routine vaccination was discontinued in 1972 was reported in 2007.⁸⁰ A 28-month-old child with refractory atopic dermatitis developed eczema vaccinatum after exposure to his father, a member of the US military who had recently received smallpox vaccine. The child's mother also developed vaccinia infection.⁸⁰

Treatment of the child included VIGIV, used for the first time in a pediatric patient; cidofovir, never previously used for human vaccinia infection; and ST-246, an investigational agent being studied for the treatment of orthopoxvirus infection.⁸⁰

The child recovered without apparent sequelae or significant scarring. Although it is difficult to assess and differentiate the effects of specific therapeutic interventions, the child's immune system almost certainly played a role in the eventual control of the infection. This case illustrates the need for meticulous prevaccination screening and the potential hazards of widespread vaccination.⁸⁰

ACAM2000, a second-generation smallpox vaccine produced in cell culture from a clonally purified master seed stock of vaccinia derived from the New York City Board of Health strain of vaccinia, has replaced the original Dryvax vaccine in the Strategic National Stockpile.^{19,36} Replication-deficient smallpox vaccines, such as the modified vaccinia Ankara (MVA), and antivirals may offer a safer, more inclusive method of addressing smallpox vaccine-associated adverse reactions, including in individuals at risk for complications.^{19,32,36,73}

Plague

Plague, a zoonotic illness caused by the gram-negative bacillus *Yersinia pestis*, is primarily a disease of rodents, with transmission occurring through infected fleas. Human disease is acquired through rodent flea vectors as well as respiratory droplets from animals to humans and humans to humans. Transmission of plague to humans in the United States primarily is by the bites of fleas from infected rodents. From 2001 to 2012, the annual number of plague cases reported in the United States ranged from one to 17 (median, three), most commonly in the southwestern United States.⁴³ Eleven cases were reported in the first 8 months of 2015 for unclear reasons.⁴³ Now an endemic zoonosis in the United States, plague is likely to continue causing rare but severe human illness in western states. Historically, plague was often linked to poor sanitation that resulted in rodent infestations.⁵⁴ However, plague in New Mexico has increasingly occurred in more affluent areas, a result of continued suburban and exurban development in enzootic plague foci.⁷² Indications of a deliberate release of plague bacilli would include the occurrence of cases in locations not known to have enzootic infection, in persons without known risk factors, and in the absence of previous rodent deaths.⁴⁵ Travelers can acquire plague in one area and become ill in another area where plague is not endemic (i.e., peripatetic plague).⁴⁴

The three clinical forms of human plague are bubonic, primary septicemic, and pneumonic. Bubonic plague, characterized by the development of an acute regional lymphadenopathy, is the most frequent clinical form and accounts for 76% of US cases.⁴³ Septicemic plague without obvious lymphadenopathy may be more difficult to diagnose than bubonic plague because of nonspecific manifestations (i.e., fever, chills, abdominal pain, nausea, vomiting, diarrhea, tachycardia, tachypnea, and hypotension).⁴⁵ Delay in establishing the diagnosis and initiating appropriate therapy may lead to death.^{43,45,58}

However, the pneumonic form would be the most likely manifestation as a result of release of an aerosol during a biologic attack.^{30,45} This clinical form is the least common, but it has the highest mortality rate; it is almost always fatal if antibiotics are not begun within 24 hours of the onset of symptoms. A 2014 outbreak in Colorado represents the largest outbreak of pneumonic plague in the United States since 1924. The source of the outbreak was a dog with pneumonic plague. Four persons developed plague after exposure to the ill dog; one of the patients

also had close contact with the index patient after he developed plague pneumonia, supporting possible human-to-human transmission.^{29,65} The incubation period for primary pneumonic plague is 1 to 3 days. Fever, chills, headache, and rapidly progressive weakness are characteristic of all clinical forms of plague. Cough, dyspnea, and hemoptysis are distinctive of primary pneumonic plague. The sudden appearance of a large number of previously healthy patients with fever, cough, shortness of breath, chest pain, and a fulminant course leading to death should suggest the possibility of pneumonic plague or inhalational anthrax immediately. The presence of hemoptysis would strongly suggest plague.^{4,45}

Y. pestis may be identified in clinical specimens by Gram, Wright-Giemsa, Wayson, and immunofluorescence staining methods in addition to standard bacterial culture. Appropriate clinical specimens include lymph node aspirates and blood as well as tracheal washes or sputum smears if pneumonic plague is suspected. Tests used to confirm a suspected diagnosis include antigen detection, immunoglobulin M enzyme immunoassay, and polymerase chain reaction assay.^{13,45} When plague is suspected, both the state and public health laboratory and public health authorities should be notified promptly.⁷⁸

Effective therapy is available in the form of streptomycin, gentamicin, chloramphenicol, doxycycline, and ciprofloxacin.⁴⁵ Parenteral aminoglycoside therapy is recommended in a contained casualty setting (modest number of patients requiring treatment); oral therapy is recommended in a mass casualty scenario.⁴⁵ The potential benefits of doxycycline and ciprofloxacin in the treatment of pneumonic plague infection in children substantially outweigh the risks.^{16,45} An inactivated, whole-cell *Y. pestis* vaccine was discontinued by its manufacturers in 1999 and no longer is available.⁴⁵

In addition to standard precautions, droplet precautions are indicated for all patients with suspected plague until pneumonia is excluded and appropriate therapy has been initiated. Droplet precautions should be continued in patients with confirmed pneumonic plague for 48 hours after the initiation of appropriate therapy.⁴⁵ Only standard precautions are recommended for bubonic plague.

Tularemia

The etiologic agent of this zoonotic illness is *F. tularensis*, a gram-negative coccobacillus. The disease may be acquired from ticks and deer flies, contact with animals such as rabbits and rodents, ingestion of contaminated water, or inhalation of aerosols.⁷⁷ In a bioterrorist event, inhalation of an aerosol would be the most likely route of infection.^{4,24} Human-to-human transmission of tularemia has never been reported. Tularemia is not a common disease, but it continues to cause approximately 100 reported human cases annually in the United States. Although outbreaks do occur, the majority of reported tularemia cases in the United States are sporadic. Approximately 40% of all tularemia cases reported to the CDC each year occur in Arkansas, Oklahoma, and Missouri. Because the distribution of tularemia may be changing gradually, it should be considered even in areas where it has rarely been reported. All suspected or confirmed cases must be reported to health authorities.⁷⁷

Clinical forms of the disease include ulceroglandular, glandular, oculoglandular, oropharyngeal, pneumonic, and typhoidal, the type reflecting the organism's portal of entry.^{26,51} Either pneumonic alone or typhoidal, with or without a pneumonic component, would be the most likely clinical manifestation of tularemia as a result of aerosol release during a biologic attack.^{4,24,77} A novel intraerythrocytic phase during *F. tularensis* infection was shown in a murine model of pulmonary tularemia.⁴² The incubation period for tularemia is 3 to 6 days, with a range of 1 to 21 days. Typhoidal tularemia may be manifested as fever of unknown origin. Standard precautions are indicated for hospitalized patients with all forms of tularemia.²⁴

The diagnosis is established most often by serologic testing, and isolation of *F. tularensis* from clinical specimens requires cysteine-enriched media or inoculation of laboratory mice. In addition to a need for special media, the laboratory should always be informed when tularemia is suspected because of the potential hazard to laboratory personnel. Suspected isolates should be confirmed by the CDC or USAMRIID through local or state health departments.²⁴

Effective therapeutic agents include streptomycin, gentamicin, tetracycline, ciprofloxacin, and chloramphenicol; postexposure prophylaxis with doxycycline or ciprofloxacin may be considered.²⁴ The benefits of tetracycline or ciprofloxacin therapy outweigh the risks in children younger than 8 years in select clinical situations, including tularemia.^{24,56} There is no vaccine available for tularemia.¹

Botulism

Seven distinct but related neurotoxins, A through G, are produced by different strains of *Clostridium botulinum*, an anaerobic gram-positive rod. The most common types in US food-borne outbreaks are A, B, and E; outbreaks with unusual botulinum toxin types (i.e., C, D, F, and G or E not acquired from an aquatic food) would suggest deliberate release.³ Classical neuroparalytic disease is acquired through the ingestion of preformed neurotoxin. Other forms include localized infection (wound botulism) and *C. botulinum* intestinal colonization in infants with in vivo toxin production (infant botulism). Botulism in the United States is seen most often in small clusters or single cases associated with home-canned foods. Although airborne transmission of botulinum neurotoxin does not occur naturally, aerosolization of preformed toxin would be the most likely route of transmission in a bioterrorism event.^{3,30} Sabotage of food supplies is also possible. Botulism is not transmitted from human to human; standard precautions are recommended for hospitalized patients.

The incubation period for food-borne botulism generally is 12 to 36 hours (range, 6 hours to 8 days). The clinical manifestations of disease acquired by inhalation would be the same as those for food-borne botulism. Early manifestations include blurred vision, diplopia, and dry mouth. Patients are afebrile with a clear sensorium.

Later clinical features indicative of more severe disease include dysphonia, dysarthria, dysphagia, ptosis, and a symmetric, descending, progressive muscular weakness with respiratory failure.³ Clinical suspicion is critical because a recognized source of exposure may be absent in a biologic attack. Botulism is a reportable disease.

A toxin neutralization bioassay in mice is used to identify botulinum toxin in serum, stool, or food. *C. botulinum* also may be cultured from stool and food. Electromyography can be helpful diagnostically. Hep-tavalent (A–G) botulinum antitoxin (HBAT) of equine origin, which has been approved by the US Food and Drug Administration and is available from the CDC, should be administered as soon as possible to patients symptomatic with botulism.^{1,3,50} A pentavalent toxoid (PBT) of *C. botulinum* toxin types A, B, C, D, and E is no longer available for use as a vaccine.⁶⁴

Viral Hemorrhagic Fever

The term viral hemorrhagic fever (VHF) refers to a clinical illness associated with fever and a bleeding diathesis caused by a virus belonging to one of four distinct families: Filoviridae (e.g., Ebola, Marburg), Arenaviridae (e.g., Lassa fever), Bunyaviridae (e.g., Rift Valley fever), and Flaviviridae (e.g., yellow fever). VHF agents are RNA viruses normally transmitted to humans from animal reservoirs or arthropod vectors. Geographic distribution of these agents is as follows: Ebola and Marburg, Africa; Lassa, West Africa; New World arenaviruses, the Americas; Rift Valley fever, Africa and the Middle East; and yellow fever, Africa and the Americas. Most of these agents are considered serious, potential biologic threats because of their potential to be aerosolized and their high morbidity and mortality rates. Clinical features vary with the specific virus, but all are capable of causing fever, myalgia, prostration, petechiae, hemorrhage, and shock.⁹

Treatment generally is supportive, although ribavirin has some in vitro and in vivo activity against arenaviruses and bunyaviruses but not against filoviruses or flaviviruses. VHF-specific barrier precautions, as well as airborne precautions, are recommended for any patient with suspected or documented VHF. Effective prophylaxis after exposure to a VHF agent is not available, although guidelines for the use of oral ribavirin as postexposure prophylaxis for Lassa fever have been proposed on the basis of an extensive review of the literature and experience in

the field.^{6,9} Clinical trials are needed to evaluate new therapies and vaccines against Ebola virus disease.²⁸

PREPAREDNESS AND RESPONSE

Being prepared for a bioterrorist attack or any other large-scale infectious disease outbreak relies on similar critical elements.^{27,47,60,66,71} Clinician awareness and education are paramount. Because practicing physicians most likely will be the first group to encounter diseases caused by biologic weapons, they must be familiar with the signs and symptoms of the more credible biologic agents (e.g., smallpox, anthrax).^{47,60,66} Recognition of an unusual case or cluster of illnesses should prompt a report to the local public health authorities.^{14,27} Improved communication between human and animal health authorities is warranted because many potential bioterrorist agents, such as anthrax, brucellosis, Q fever, plague, and tularemia, are zoonotic diseases.²⁷ Knowledge of the processes by which the hospital laboratory, the local or state health department, or the CDC performs diagnostic studies to implicate or to exclude biologic agents also is important.^{7,27,47} Local, state, and federal public health agencies must coordinate plans for dealing with a large-scale outbreak caused by a biologic event.^{7,14,27,71} They should address rapid investigation of the outbreak, public education, mass distribution of antibiotics and vaccines, the capacity to care for mass casualties, and proper, expeditious treatment of the dead.^{7,27,47,71}

Laboratory tests can lead to or confirm diagnoses as well as aid in choosing appropriate therapy. The challenge of the clinical diagnostic laboratory is to provide accurate, clinically relevant information in a timely manner. However, a recent report by the Institute of Medicine highlighted the fact that diagnostic errors are underappreciated and occur with unacceptable frequency.⁴⁶ Effective collaboration between physicians and laboratories is key to minimizing this type of error. To this point, laboratory diagnosis of bacterial infections begins at the bedside, not in the laboratory, with the appropriate collection and transport of specimens. This initial step is critical in making an accurate laboratory diagnosis, as no level of technical expertise or amount of specialized technology can correct for an improperly collected or transported specimen. Most bacteriology testing depends on the cultivation and identification of living organisms, and as such, more than any other area of the clinical laboratory, microbiology is affected by inappropriate specimen management practices. Examples of common problems include incorrect or insufficient specimen labeling, insufficient volume of specimen collected, incorrect transport media, and delays in transport of the specimen to the laboratory. Some common principles for quality specimen collection and transport are listed in [Box 251.1](#).

CULTURE-BASED DETECTION

Whereas technologic advancements have been made in the area of direct pathogen identification by use of molecular methods and mass spectrometry, the isolation of live organisms is still critical, in particular because of the need to determine antimicrobial susceptibility results. Bacterial culture depends on the growth of organisms on various different types of culture media, including selective, differential, and enriched.

Each particular type of specimen has distinct requirements for optimal collection and transport as well as recommended media types to support growth of suspected organisms. The individual specimen-specific collection and cultivation requirements, as well as strategies for identification and diagnosis of various bacterial infections, are described in the following sections.

Specimen-Specific Collection and Cultivation Requirements

Bloodstream Infection

Sepsis has long been associated with significant morbidity and mortality; according to the Centers for Disease Control and Prevention (CDC) National Center for Health Statistics, sepsis was the 11th leading cause of death in the United States in 2013.¹⁰⁰ Given the significant impact of sepsis, the detection of microorganisms circulating in the bloodstream of a patient is among the most critical roles of the clinical microbiology laboratory. Detection of bacterial pathogens is typically accomplished through the incubation of a blood sample in a bottle that contains a specialized liquid medium on a continuously monitored blood culture system. A positive blood culture can confirm a cause of the septic event as well as allow appropriate antimicrobial susceptibility testing and thus optimal antibiotic therapy. The automated blood culture systems routinely used in microbiology laboratories are described as continuously monitored because the system takes periodic readings to evaluate possible growth of microorganisms. Several systems are currently available with differences in detection methods, but all perform comparably. This constant monitoring is accomplished without entering the bottle, and thus the contamination rate for these systems is lower than that of the lysis-centrifugation system (Isolator, Wampole Laboratories).

The single variable with the greatest impact on the sensitivity of detection of bacterial pathogens in blood is the volume of blood that

is cultured.^{22,56} Whereas this observation is based primarily on data from studies of adult patients, several studies show that increasing the volume of blood cultured increases the sensitivity of detection in a pediatric population as well.^{23,30} In addition, multiple studies have demonstrated that low-level bacteremia in pediatric patients is common, and thus by increasing the volume of blood cultured, the likelihood of detecting low-level bacteremia increases.⁴⁹ Because pediatric patients have a wide range of blood volumes, there is not one recommended volume for optimal blood culture collection. The most common approach to guiding appropriate volume of blood cultured from pediatric patients is the implementation of a weight-based guideline.³⁸

As is the case with any specimen, blood cultures should be transported to the laboratory in a timely manner. Several studies have shown that delays in entry of blood culture bottles to the blood culture system can result in falsely negative cultures (decreasing sensitivity of detection) and increases in time to detection (delaying the reporting of positive results).⁸² Optimally, the blood culture bottle should be loaded onto the blood culture system within 4 hours of collection. If delay in entry to the blood culture system is required, during the delay time, the sample should not be incubated at 37°C (98.6°F) because preincubation may significantly compromise results.⁹⁵ Optimal temperature for transport of blood culture bottles is room temperature.

Before the introduction of automated, continuously monitored blood culture detection systems, the detection of certain fastidious organisms required incubation times up to 2 weeks. However, with use of the automated systems, both routine and fastidious organisms will be detected within a 5-day incubation time. This 5-day incubation time is adequate for detection of fastidious organisms such as *Brucella*, *Francisella*, *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella*, *Abiotrophia*, and *Granulicatella*.^{21,96} Importantly, there are limitations to the routine blood culture; for example, *Streptobacillus moniliformis* is sensitive to even low levels of the anticoagulant SPS, which is added to some aerobic blood culture bottles. In cases with suspected rat-bite fever, the recommendation would be to include an anaerobic blood culture bottle because the anaerobic bottles contain a lower level of SPS.⁸⁵ Certain organisms are so slow growing that they will likely be missed with the routine 5-day incubation time of a standard blood culture; examples of these pathogens are filamentous fungi, *Nocardia* spp., and slow-growing mycobacterial species. Because these microorganisms do require longer incubation times and different media than the routine blood culture provides, it is best to send separate specimens for specialized fungal or mycobacterial testing if these organisms are suspected.

After the blood culture is flagged as positive, organism identification and susceptibility testing can be performed. Although traditional identification and antimicrobial susceptibility results can take up to 48 hours to obtain, the introduction of mass spectrometry and molecular technologies to the clinical microbiology laboratory has dramatically decreased the time to definitive organism identification.³¹ Several rapid molecular tests are available that can identify organisms to species or genus level and for a limited number of drugs can provide information on antimicrobial resistance.¹¹ Two examples of gram-positive organisms with known resistance phenotypes that can be identified with rapid molecular tests are *Enterococcus faecium* resistant to vancomycin and *Staphylococcus aureus* resistant to methicillin. For gram-negative organisms, although information regarding species-level identification can be obtained, there are no molecular assays that can predict susceptibility. Importantly, the addition of rapid identification by molecular tests or mass spectrometry does not replace the need to grow the organism in order to perform traditional susceptibility testing.

BOX 251.1 Principles for Quality Specimen Collection and Transport

Use sterile technique to minimize contamination.
 Collect as close to the site of infection as possible.
 Collect at optimal times to recover the pathogens of interest.
 Obtain a sufficient quantity of the specimen to perform the requested tests.
 Use appropriate collection devices and specimen containers to ensure recovery of all organisms.
 Collect all microbiology specimens before the institution of antibiotics.
 Properly label and seal the specimen container before transport.
 Minimize transport time or maximize transport media. There is always some loss of viability during transport.

Respiratory Tract Infections

Although most respiratory tract infections have viral causes, the focus of this chapter is on bacterial pathogens. The laboratory diagnosis of respiratory tract infections is complicated by the fact that the respiratory tract is normally colonized with a complex and robust microbiologic community. Importantly, many of the organisms that are normal colonizers of the respiratory tract can also be pathogenic when they are overgrown or out of balance with the normal ecology of the respiratory tract. Common components of normal respiratory flora that are also respiratory tract pathogens include but are not limited to *Streptococcus pneumoniae*, *Haemophilus influenzae*, *S. aureus*, *Neisseria meningitidis*, and *Moraxella catarrhalis*. It is important to note that the newly available, highly sensitive molecular panels for identification of respiratory pathogens may include bacterial organisms that can be components of normal flora. The significance of a positive molecular result in the setting of existing normal respiratory flora is complicated and must be interpreted with caution.

For the purposes of laboratory testing, the respiratory tract is divided in two on the basis of anatomy; the upper respiratory tract includes the areas from the anterior nasal passages to the larynx, and the lower respiratory tract includes the structures beyond the larynx. Typically, samples collected from the upper respiratory tract include swabs and washes and are not considered sterile, whereas samples collected from the lower respiratory tract typically require more invasive collection techniques, such as bronchoalveolar lavage or lung biopsy, and may be considered sterile. Because of the difficult and invasive nature of true lower respiratory specimen collection, laboratories often accept specimens that require less-invasive techniques, such as expectorated sputa or tracheal aspirates, in an effort to diagnose a lower respiratory tract infection. However, these less-invasive specimens are not sterile and must be considered in the context of normal respiratory flora.

Upper respiratory tract infections account for more physicians' office visits than any other type of infection,¹⁸ and although most of these infections are the result of viral infections, bacterial etiologies are also important. Examples of infections that fall into the "upper respiratory" category include pharyngitis, otitis media, and otitis externa.

The etiology of pharyngitis can be made by culture and nucleic acid or antigen-based methods. Typically, the specimen is collected on a throat or oropharyngeal swab; swabs made of synthetic fibers are optimal, and there may be an advantage to use of a flocked swab for optimal sample collection.⁴¹ In the pediatric patient population, agents other than *Streptococcus pyogenes* (group A streptococcus) can cause pharyngitis and must be considered. Not all laboratories routinely identify organisms other than group A streptococci (GAS), and thus special requests should be made to ensure appropriate testing. In addition to GAS, large colony-forming, β -hemolytic organisms from the Lancefield groups C and G, as well as *Arcanobacterium haemolyticum*, may cause pharyngitis with clinical symptoms similar to those of GAS pharyngitis.⁹⁴ Detection of GAS nucleic acid by various molecular methods has been shown to offer superior sensitivity to antigen-based detection. However, these tests are unable to distinguish whether the presence of GAS nucleic acid reflects organism carriage or the cause of pharyngitis. An argument against the routine use of molecular methods is the potential for high

numbers of false-positive results due to GAS detection in asymptomatic carriers. Therefore it is important to highlight that the use of any GAS diagnostic test requires adherence to clinical guidelines detailing the indications for testing.³⁵

Otitis externa and otitis media are usually diagnosed clinically and managed empirically; however, in cases of spontaneous perforation of the tympanic membrane or when myringotomy/tympanocentesis is performed, fluid can be sent for culture and microbiologic evaluation. Fluid is the optimal specimen for bacterial culture. Nasopharyngeal specimens are not representative of the etiologic agents of otitis media.⁴³

Laboratory diagnosis of lower respiratory tract infections, primarily pneumonia, is complicated by the difficulty of collecting appropriate lower respiratory tract samples. In addition, delays in transport of specimens to the laboratory may result in overgrowth of significant pathogens by nonpathogenic colonizing flora or the loss of significant pathogens.^{16,67} Whereas organisms isolated from specimens such as pleural fluid or tissue from lung biopsy must always be considered significant, these highly invasive procedures are relatively rarely performed. The most common specimens collected to aid in diagnosis of pneumonia include sputa and tracheal washes or aspirates. Results from cultures of these specimen sources in any scenario are complicated by the presence of normal upper airway flora, and the determination of significance for any given isolated organism is difficult.¹⁶ To aid in the determination of the quality of either sputa or bronchial aspirate specimens, laboratories perform microscopy-based screening of specimens and reject samples that are not adequate. Specimen quality is evaluated on the basis of the presence and quantity of organisms, squamous epithelial cells, and polymorphonuclear leukocytes. A large number of squamous epithelial cells represents oropharyngeal contamination, and these specimens should be rejected with a recommendation for recollection (with the exception of cases in which *Legionella* or mycobacterial infections are suspected).⁸⁶ The presence of large numbers of polymorphonuclear leukocytes can indicate a quality specimen; however, there are exceptions to this observation. In the case of tracheal secretions or aspirates from ventilated, low-birth-weight infants, large numbers of polymorphonuclear leukocytes were associated with the length of intubation and not the development of respiratory symptoms.⁸⁶ Although bronchoalveolar lavage is not as commonly performed because of the more invasive nature of the procedure, bronchoalveolar lavage specimens provide quality lower respiratory tract samples. The procedure includes the wedging of the bronchoscope channel into an airway lumen followed by the injection of saline through the lumen. The injected saline is aspirated out in several aliquots. The initial aliquot removed will be contaminated with upper airway secretions and should be discarded before bacterial culture. In an effort to aid in establishing significance of various pathogens isolated from bronchoalveolar lavage cultures, some laboratories perform quantitative cultures and establish cutoffs for significance.¹³

Central Nervous System Infections

Because of the significant morbidity and mortality associated with bacterial meningitis, the rapid and timely identification of the causative agent is critical. Cerebrospinal fluid (CSF) specimens are collected by lumbar puncture and must be transported to the laboratory at room temperature and processed without delay. Owing to the rapid changes in the pH of the CSF on removal from the patient and the hypotonic nature of CSF, the viability of microorganisms is reduced as time passes, potentially increasing the likelihood of false-negative culture results³⁸; in addition, host cells may lyse, resulting in an altered cell count. If sequential tubes of CSF are collected, the first tube is not ideal for microbiologic studies because of the possibility of contamination with skin flora or blood from the initial lumbar puncture, which can alter culture results. The second tube should be sent for microbiologic studies whenever possible. Although bacterial stain and culture can be performed on small amounts of fluid, it is recommended to send larger amounts of CSF because of the typically low number of microorganisms present in the specimen. For isolation of mycobacteria from CSF, a minimum of 5 mL of specimen is recommended.³

On receipt into the laboratory, CSF specimens should be routinely Gram stained and set up for bacterial culture. Sensitivity of the Gram

stain can be improved by concentrating the specimen by cytocentrifugation before staining.⁸⁴ Positive Gram stain results can offer useful information about organism morphology and Gram stain phenotype; but large numbers of organisms are needed for visualization, and a negative Gram stain result does not indicate a lack of pathogenic organisms in the CSF.⁵³ Staining with acridine orange (a fluorescent stain) increases the sensitivity of detection of microorganisms, but this stain does not provide information about the Gram-stain phenotype (e.g., gram positive or gram negative).^{52,55} CSF specimens should be inoculated onto both chocolate agar and sheep blood agar and incubated for 72 hours. Routine inoculation of broth-based media is not necessary and may result in isolation of contaminants.^{65,90} Inoculation of broth media may add value in cases in which anaerobic or other unusual organisms are suspected or when hardware is in place. Direct bacterial antigen testing of CSF by latex agglutination is not recommended.⁷²

Although CSF culture is the diagnostic reference standard for bacterial meningitis, the sensitivity is limited (ranging from 70% to 90%), particularly when antibiotics have been previously administered.⁷⁹ Nucleic acid amplification tests, such as polymerase chain reaction (PCR)-based multiplex panels, offer a high level of sensitivity and specificity and, as such, have significant utility in detecting pathogens from a single CSF sample. Additionally, the amplification of DNA from nonviable bacteria could potentially facilitate diagnosis in culture negative cases.^{51,66,97,99} The Film Array Meningitis/Encephalitis (ME) Panel (BioFire Diagnostics) is the only US Food and Drug Administration (FDA)-cleared PCR-based panel for detecting pathogens including bacteria, viruses, and yeast from CSF specimens obtained from patients with signs and symptoms of meningitis or encephalitis. Importantly, because of the need to perform antimicrobial susceptibility testing, nucleic acid testing should only be considered as an adjunct to routine bacterial culture.⁷⁰

Urinary Tract Infections

Pediatric urinary tract infections are most commonly caused by gram-negative enteric bacteria. *Escherichia coli* causes 80% of infections. Other common pathogens include but are not limited to *Klebsiella* spp., *Proteus* spp., *Enterobacter* spp., group B streptococcus and *Enterococcus* spp., and occasionally *Pseudomonas* spp.^{6,102} As is the case for respiratory tract pathogens, urinary tract pathogens must be isolated and identified in and among a background of other normal bacterial flora. To distinguish organisms that colonize the distal urethra from true urinary tract pathogens, quantitative bacterial culture is performed on urine specimens. A recent meta-analysis evaluating the impact of preanalytic practices on diagnostic accuracy of urine cultures emphasized that midstream collection with cleansing is ideal⁵⁴; however, these specimens are difficult to obtain in many pediatric age groups. Catheterized specimens are an acceptable choice for patients in whom the clean-catch method is not possible. Soiled diapers and urine collected by affixing a bag to the perineum are not acceptable specimens. To prevent misleading results, it is important that urine specimens be kept refrigerated if they are not inoculated in a timely manner (<2 hours); in cases of prolonged storage of urine at ambient temperature, false-positive culture results can be obtained. Regardless of the specimen, a known volume of urine, 0.001 mL for catheter samples or clean-catch samples, is inoculated onto plate media. This plating technique allows the number of colony-forming units (CFU) per milliliter of urine to be quantified. Current recommendations based on previous studies state that 50,000 CFU/mL of a single uropathogenic organism in a properly collected urine specimen in the presence of pyuria is indicative of a urinary tract infection.⁹¹ Any quantity of bacterial growth from urine collected through a suprapubic aspiration is considered significant.

Gastrointestinal Infections

The most common manifestation of gastrointestinal (GI) infection in pediatrics is acute diarrhea, and as is the case with pharyngitis, the most common cause is not bacterial. Viral, parasitic, or immune-related issues most commonly cause diarrhea. However, the ability to rule out a bacterial cause is critical, and thus the clinical microbiology laboratory must have appropriate processes in place to isolate and to identify bacterial stool pathogens. Feces should be collected in a sterile container and transported to the laboratory in a timely fashion to avoid overgrowth

with normal flora and the potential loss of pathogenic organisms. If rapid transport to the laboratory is not possible, transport media such as Cary-Blair can be used to stabilize the organisms during transport to the laboratory. Because of the presence of high quantities of commensal flora in feces, stool cultures require a combination of both selective and differential media to identify potential pathogens. Most standard stool cultures will include at least two selective and differential media types; commonly used media formulations for the isolation of pathogens such as *Salmonella* and *Shigella* include but are not limited to MacConkey agar, xylose-lysine-deoxycholate agar, and Hektoen enteric agar. Other examples of media formulated for the detection of specific stool pathogens are cefsulodin-irgasan-novobiocin (CIN) agar for isolation of *Yersinia* species, thiosulfate–citrate–bile salts–sucrose (TCBS) agar for the isolation of *Vibrio* species, and Campylobacter agar for the isolation of *Campylobacter jejuni* and *Campylobacter coli*. Another important pediatric enteric pathogen is Shiga toxin-producing *E. coli* (STEC); most reported STEC infections in the United States are caused by *E. coli* O157:H7, with an estimated 73,000 cases occurring each year.⁶³ Non-O157 STEC organisms can also cause diarrheal illness and have been associated with outbreaks and sporadic illness.⁴⁸ Direct plating methods for the detection of *E. coli* O157:H7 should be performed on a selective and differential agar, such as sorbitol-MacConkey agar (SMAC), cefixime-tellurite-sorbitol-MacConkey agar (CT-SMAC), or CHROMagar O157. The toxin genes can be detected by molecular methods, or toxin can be detected by enzyme immunoassay after broth enrichment.⁴²

There is no single definition of what pathogens are routinely screened for in the stool culture. Owing to the variability in the stool culture process, the clinician must inquire as to what pathogens are routinely screened for and which pathogens may require a request for specialized culture methods in the testing laboratory.

Several recently developed PCR-based, multiplex GI panels offer a reduction in time to result and detect a broad range of organisms including bacterial, viral, and protozoal pathogens. The three FDA-cleared nucleic acid based syndromic GI panels—xTag GI Pathogens Panel (GPP) (Luminex), FilmArray GI Panel (BioFire Diagnostics), and Verigene Enteric Pathogens test (Nanosphere)—detect *Campylobacter* spp., *Salmonella* spp., *Vibrio* spp., *E. coli* O157, *Yersinia enterocolitica*, *Shigella*, and bacterial toxin (STEC), whereas *Plesiomonas shigelloides* and *Aeromonas* spp. are only included in the FilmArray panel.¹⁰¹ Implementation of these panels has been shown to increase pathogen detection and has potential to reduce nosocomial transmission events and decrease inappropriate antibiotic therapy.^{7,12,71,80,87} However, given that these are culture-independent methods, no antimicrobial susceptibility data are available with a positive result. The absence of susceptibility results may have a greater impact on pediatric patient populations because infants and children are more likely to need antimicrobial therapy than adults. Specifically for cases of salmonellosis or shigellosis, the resistance profile of these pathogens varies widely, and appropriate therapy requires susceptibility testing.²⁶ Clinical laboratories that offer these multiplex panels may perform reflex bacterial cultures as needed so that susceptibility testing can be completed, but this is not a standard practice, and as such the clinician should be aware of the laboratory practices before ordering these molecular tests.²⁶ Additionally, these panels may not be appropriate in certain situations such as hospital-onset diarrhea, for which *Clostridium difficile* testing might be all that is required. A final consideration is whether these panels should be restricted to certain patient populations (e.g., immunocompromised) or made available to all.^{9,57}

NON-CULTURE-BASED DETECTION METHODS

Several non-culture-based approaches are used to detect bacterial infections, including microscopy, detection of bacterial antigens or antibodies against the organism, and detection of nucleic acids by molecular methods. A detailed overview of these detection methods for bacteria is provided in this section.

Microscopy

Direct microscopic observation of the specimen is a simple yet reliable technique for demonstrating the presence of microorganisms as well

as inflammatory cells in the specimen. Differential (Gram, Kinyoun, Giemsa) and fluorescent (acridine orange, auramine-rhodamine) stains are most commonly used. The Gram stain is a rapid, inexpensive method for assessing the presence of an etiologic agent in the specimen. Preliminary assessments from a stained specimen can indicate the Gram phenotype (positive or negative), the morphology (cocci vs. bacilli), and the spatial arrangement (clusters, chains, or diploid formation). Other differential stains routinely used for bacterial identification are the Kinyoun stain for *Mycobacterium* spp., the modified Kinyoun stain for *Nocardia* spp. and *Streptomyces* spp., and the Wright-Giemsa stain for bacteria (*Borrelia*) or bacterial inclusions (*Anaplasma*, *Ehrlichia*) in clinical specimens. Fluorescent stains are generally more sensitive than differential stains; however, the Gram phenotype is not available by this type of stain. Although useful information may be collected through a positive direct stain, a negative stain result does not rule out the presence of microorganisms, and thus all direct bacterial stains should be followed by culture.

Mass Spectrometry

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) is a technology that provides rapid identification of a variety of pathogens isolated from clinical specimens within hours.^{15,27} This technology uses unique protein spectral profiles of the microorganisms to identify organisms based on known catalogued databases of these profiles.^{24,29,40} In contrast to traditional biochemical-based methods of identification of microorganisms, MALDI-TOF-MS allows the identification of organism with minimal culture growth and as such shortens the time to identification significantly.^{8,31,64} Two commercially available MALDI-TOF-MS platforms are cleared by the FDA for organism identification on culture isolates, but no system has yet been cleared for organism identification of direct specimens.^{14,36,83,89}

Molecular Diagnostic Techniques

Nucleic acid amplification tests (NAATs) detect bacterial nucleic acid from either direct specimen or cultured bacterial isolates. NAATs have become increasingly important tools for the detection and identification of infectious diseases. The introduction of nucleic acid–based testing has provided increased sensitivity of detection and decreased time to detection for many bacterial pathogens. Molecular tests that are widely used in clinical microbiology include both highly complex tests that require specialized staff and are performed in batches as well as the more recently available “on demand” assays that can be performed in a more clinically relevant time period and by nonlaboratory personnel. Molecular techniques can be particularly useful for the detection and identification of fastidious organisms (those that have specialized growth conditions or are slow or noncultivable under laboratory conditions). There are numerous molecular tests to aid in the identification of poorly cultivable or atypical organisms, including *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Mycobacterium tuberculosis*, *Bordetella pertussis*, *Bartonella henselae*, *Mycoplasma pneumoniae*, and many others. The number of pathogens that can be detected by NAATs is rapidly increasing, as are the specimen types from which molecular testing can be performed.

Molecular Methods for Atypical Organisms

Bordetella pertussis

Although infection with *B. pertussis* can occur at any age, babies younger than 6 months, infants, and young children are at highest risk.⁶⁹ *B. pertussis* infection mostly remains a clinical diagnosis; however, laboratory detection is often sought for confirmation. Isolation of the organism by culture has been the historical standard test for confirmation of diagnosis and is essential if evaluation of antimicrobial resistance is required. However, successful isolation of the organism declines significantly beyond the first 2 weeks of illness and with prior antibiotic therapy.^{33,92} Furthermore, *B. pertussis* is fastidious and requires 3 to 6 days of incubation to form detectable colonies by culture. *B. pertussis* often will not grow if cultures are not initiated within 48 hours of sample collection.⁵⁹ As per CDC recommendation, PCR detection of *B. pertussis* DNA has become increasingly available for the timely diagnosis of pertussis.⁵ Optimal specimens for PCR testing include

nasopharyngeal swabs and aspirates. Throat swabs and anterior nasal swabs have low rates of DNA recovery and should be avoided for *B. pertussis* testing.⁵ The increased specificity and rapidity of PCR testing allow the results to be available within 24 to 48 hours. There are currently no FDA-approved *B. pertussis* PCR assays, and there are no standardized protocols, reagents, or reporting formats for *B. pertussis* PCR testing. Consequently, PCR assays vary widely among laboratories. Most *B. pertussis* PCR assays use a single DNA target, the insertion sequence IS481 that is present in multiple copies in the *B. pertussis* chromosome and in fewer copies on the chromosomes of *Bordetella holmesii* and *Bordetella bronchiseptica*.⁸¹ The presence of IS481 in the chromosomes of nonpertussis strains can lead to false positivity.³⁷ Therefore interpretation of PCR results should be done carefully in conjunction with evaluation of clinical symptoms.

Tuberculosis

The poor sensitivity of standard laboratory tests for the detection of *M. tuberculosis* is a major obstacle to diagnosis of tuberculosis in children. In addition, the nonspecific clinical presentation, paucibacillary nature of pediatric disease, and inability to expectorate sputum in children further complicate the laboratory diagnosis of tuberculosis.⁵⁰ Adequate clinical specimens are often difficult to obtain from children younger than 8 years because of lack of sputum production, and first-morning gastric aspirates are an important specimen for pediatric patients.⁸⁸ Even with best practice, *M. tuberculosis* is isolated in less than 50% of clinically suspected pediatric cases.¹ Therefore most cases are still diagnosed on the basis of clinical and radiographic findings. However, rapid laboratory confirmation of tuberculosis can lead to earlier treatment initiation, targeted antimicrobial therapy, and better clinical outcomes.¹⁰ Tests based on nucleic acid amplification have become an important tool for the diagnosis of tuberculosis and, when results are positive, can detect *M. tuberculosis* directly from a specimen with a rapid turnaround time of hours or days in contrast to the weeks required with culture. Whereas the currently available molecular methods are rapid and have excellent specificities, their sensitivities do not equal those of culture-based methods, particularly in cases of smear-negative specimens.^{58,73} Unfortunately, most pediatric tuberculosis cases are smear negative.

Several molecular methods for detection of tuberculosis are FDA cleared or approved. The enhanced amplified *M. tuberculosis* direct test (E-MTD, Gen-Probe) and the Amplicor *M. tuberculosis* test (Roche Diagnostic Systems) are FDA approved for detection of *M. tuberculosis* complex in smear-positive respiratory specimens.^{58,73} The Gen-Probe test is also approved for use with smear-negative respiratory specimens from patients thought to have tuberculosis. The E-MTD test (isothermal transcription mediated) and the Amplicor test (PCR based) rely on amplification of a portion of the 16S rRNA followed by hybridization and detection of a probe specific for *M. tuberculosis* complex bacteria. None of these tests has been approved for direct detection from extrapulmonary specimens. There are no specific recommendations made on the use of molecular testing in the diagnosis of tuberculosis in children who cannot produce sputum and in the diagnosis of extrapulmonary tuberculosis.

Clostridium difficile

Laboratory methods for detection of *C. difficile* have undergone considerable evolution since the organism's etiologic association with antibiotic-associated infectious diarrhea and pseudomembranous colitis or *C. difficile*–associated disease in hospitalized patients was established. The diagnostic gold standards for *C. difficile* detection included anaerobic bacterial culture coupled with toxin detection or tissue culture cytotoxic assay, both of which are time-consuming, expensive, and technically challenging.¹⁴ Although rapid detection kits (i.e., immunoassay) are commercially available, they lack sufficient sensitivity and specificity without serial testing.^{17,25,32} The emergence of community-acquired *C. difficile* cases without antecedent antibiotic exposure in addition to the emergence of a quinolone-resistant “hypervirulent” strain of *C. difficile* (designated BI/NAP1/027) in adult and pediatric patients led to significant technical improvements in diagnostic laboratory testing.^{62,74} One diagnostic approach to the identification of *C. difficile* is to use a rapid,

real-time PCR-based molecular assay that targets the disease-producing *C. difficile* toxin genes. Factors that decrease the viability of organisms (e.g., treatment with antibiotics) lower the sensitivity of detection for culture and rapid immunoassays, but loss of viability does not affect molecular assays. There are currently at least 12 FDA-cleared assays available for detection of *C. difficile*.² Most methods are based on real-time PCR with the following exceptions: illumigene *C. difficile* assay (Meridian Bioscience), a loop amplification-based method; and Portrait Toxigenic assay (Great Basin Corp.), an isothermal amplification and chip-based method. All these tests yield results in fewer than 24 hours, with sensitivities reported at greater than 95% and negative predictive values of 99%.^{4,93} However, positive *C. difficile* PCR assays on stool specimens in infants younger than 12 months usually represent colonization, and testing should be performed in infants only when other possible causes of diarrhea have been ruled out.⁸

Neisseria gonorrhoeae and Chlamydia trachomatis

Adolescents and young adults have higher rates of infection with *Chlamydia trachomatis* (CT) and *Neisseria gonorrhoeae* (GC) than any other age group does,⁷⁵ and nucleic acid amplification testing has greatly facilitated sensitive and specific screening in this population. These assays are extremely sensitive with a limit of detection as low as a single gene copy.^{19,39} In addition, testing of urine specimens offers noninvasive sample collection. These tests provide the ability to test for both GC and CT in the same specimen. The most commonly used FDA-approved assays are for testing on cervical swabs from women and urethral swabs and urine from men and women. Importantly, none of these assays is approved for testing of specimens from children. The identification of sexually transmitted diseases like *C. trachomatis* and *N. gonorrhoeae* infections in children should raise suspicion for sexual assault, and there are both medical and legal implications to the diagnosis of sexually transmitted diseases in infants and children.⁴⁴ Thus testing requires the use of a highly specific method; the gold standard for detection of GC/CT in children and infants has been culture from appropriate specimens.⁹⁸

Sequence-Based Technologies

Sequence-based technologies have been used to improve the speed and accuracy of identification of organisms that are difficult to identify by conventional methods or to detect and identify uncultivable organisms. New high-throughput sequencing technologies, also known as next-generation sequencing, have replaced the commonly used Sanger sequencing for clinical microbiology application.^{45,61,76} For bacterial identification, 16S ribosomal genes are common targets of interest.²⁰ There are several open-access ribosomal sequence databases that can be used to produce alignments of the 16S ribosomal sequences and subsequent species assignment. By comparing the organism's 16S rRNA gene sequence with sequences found in databases of known organisms, the identity of etiologic agents from clinical specimens can be successfully determined.^{20,34,47,68} Other technologies, such as pyrosequencing and single-cell and whole-genome sequencing methods, are also promising and powerful tools in clinical microbiology.^{60,77,78} These methods are able to generate megabases of sequence information about the whole organism yet are currently in the research use-only phase and are not widely used in diagnostic microbiology laboratories.

Historically, fungi were regarded as insignificant causes of infection. The dramatic increase in invasive fungal infections has been directly related to organ transplant recipients, particularly during the post-transplantation period, and patients with malignant neoplasms and debilitating immunologic or metabolic disorders, such as systemic lupus erythematosus, diabetes mellitus, and alcohol or injection drug abuse.

Until recently, fungi were allowed to carry multiple scientific names based on the sexual (teleomorph) and asexual (anamorph) stages of their life cycle. In many cases, it was difficult to establish the relationship of these forms. As of 2013, the dual naming is no longer permitted, so there will only be one name for a fungus. The main criteria for classification are genetic rather than phenotypic.³ This may affect species names of medically important fungi.

SPECIMEN COLLECTION

When an infectious process is suspected, the most appropriate tests directed toward the detection of the etiologic agent must be ordered. Knowledge of the pathophysiology of the disease process is important in determining the type of specimen and optimal time for specimen collection. These collections must include sufficient quantity of specimens for culture, direct microscopy and detection of the etiologic agent using antigen tests, molecular tests, special stains, and antibody methods. All specimens should be considered hazardous, and universal precautions must be used for all specimen collection procedures. Procedures used for specimen collection for direct detection or culture of bacteria can be used for fungi (Table 252.1).^{2,4} Microbiologists and pathologists are available to guide physicians in selecting the most appropriate specimen for culture and other tests to achieve rapid detection and recovery of the microorganism causing the infection. Most clinical laboratories have established guidelines for specimen collection with minimal volumes of specimen to be collected. In addition, specimens should be collected in sterile containers before the initiation of therapy to ensure that optimal recovery of organisms is achieved. Specimens collected for 24 hours, such as urine and sputa, are unsuitable for fungal culture because of bacterial overgrowth. Swab specimens are considered inadequate for the recovery of fungi, particularly when multiple culture tests (bacteriology, mycology, mycobacteriology, and virology) from the same swab specimen are requested. In many instances, surgeons send tissue for a histologic diagnosis and neglect to submit a request for culture. If an infection caused by a dimorphic fungus such as *Coccidioides immitis* is suspected, the physician should notify the laboratory because of hazards associated with culture of this organism. A poorly collected specimen may result in the failure to recover the organism, or it may lead to therapy directed at a contaminating or commensal organism.

Specimens should be transported to the laboratory as soon as possible under optimal conditions, which usually are advised in the laboratory specimen collection manual that should be available to all physicians. Specimen transport and storage at room temperature is recommended. Ideally, specimens should be received in the laboratory within 2 hours of being collected. If a delay occurs in setting up cultures, the specimen should be held at room temperature or 4°C (39.2°F) to prevent bacterial overgrowth. Unacceptable specimens that should not be processed include specimens in containers that leak, specimens received many days after collection, and specimens held under inappropriate temperature conditions. Some fungal isolates, such as *Cryptococcus* spp. and *Histoplasma capsulatum*, do not survive well at refrigerated or freezing temperatures.

DIRECT DETECTION

In the laboratory, direct wet mounts or smears can be prepared, and a portion of the specimen can be used for culture (Table 252.2). Blood, cerebrospinal fluid (CSF), and urine also can be used for the detection of antigens and nucleic acids by enzyme immunoassay, lateral flow devices, latex agglutination, magnetic resonance, polymerase chain reaction, and radioimmunoassay.^{1,2,4-9} These assays have proved useful for the detection of infections caused by *Aspergillus* spp., *Blastomyces dermatitidis*, *Cryptococcus neoformans*, and *H. capsulatum*. Although molecular methods may be used for the direct detection of fungal infections (Table 252.3), most have been validated in specific laboratories as a laboratory developed test (LDT) for clinical use but are not readily available in most clinical laboratories. Direct microscopic examination, including frozen sections of tissue to provide an immediate presumptive diagnosis, should be performed on most specimens. A definitive diagnosis may be made when specific fungal elements pathognomonic for fungal infections are detected in direct specimen stains. Examples include *Blastomyces dermatitidis*, *C. neoformans*, *Coccidioides posadasii*, *C. immitis*, and *Pneumocystis jiroveci*. Detection of wide and narrow, wavy, or ribbonlike nonseptate hyphae is consistent with a *Mucorales* spp. infection. Direct specimen examinations always must be followed with culture because the direct examination can never be used to rule out infection, and recovery of the organism may be necessary for speciation or susceptibility testing.

Fungemia can be directly detected from whole blood using the T2Candida magnetic resonance method.⁷ Candida can be directly detected from blood culture broth in approximately 1 hour using the FilmArray Blood Culture Identification kit or Candida QuickFISH BC method.^{6,8} Although the number of *Candida* species detected are limited, these methods are significant improvements in direct detection of etiologic agents causing serious infections and use of antifungal therapeutics.

Serology may be used to diagnose fungal infections because either other direct detection methods were negative or the organism failed to grow in culture. In general, serology is not as sensitive as are other direct methods, such as antigen detection, particularly in immunocompromised patients. Serology has been useful in the diagnosis of *C. immitis*, *C. posadasii*, and *H. capsulatum* infections and can be used to follow successful therapy in coccidioidomycosis.⁹ Serologic methods include complement fixation, enzyme immunoassay, immunodiffusion, lateral flow devices, and latex agglutination.

During infections, fungal cell wall antigens are released into surrounding tissue and body fluids (blood, CSF, respiratory secretions, and urine).⁹ The results from antigen-based tests are much more rapid than culture. Their detection can be useful in supporting a clinical diagnosis when culture and histopathology are negative. Detection of glucuronoxylomannan has been successfully used to diagnose and follow *C. neoformans* and *Cryptococcus gattii* infections. This test is highly sensitive, and circulating capsular polysaccharide can be quantitated to determine a patient's therapeutic response.

Invasive aspergillosis is a diagnostic challenge, and the development of a galactomannan test (polysaccharide cell wall component of *Aspergillus*) had been helpful in certain patient populations. Test results have better predictability among patients with hematologic malignancies than among those receiving a solid-organ transplant. False-positive test results are common in lung transplant recipients. Urine antigen tests for the diagnosis of blastomycosis, coccidiomycosis, and histoplasmosis are sensitive and more rapid than culture or serologic results. Other fluids can be used with these tests for detection of blastomycosis and histoplasmosis, but

TABLE 252.1 Specimen Collection Guidelines

Specimen	Recommendations	Transport Device/Comments
Abscess/wounds	Collect as per bacterial culture.	Collect in sterile container with as much material as possible. If swab is used, use exclusively for mycology. RT
Blood	Use fungal media for mold recovery and collect as per product insert. Yeast (<i>Candida</i>) can be readily recovered from bacterial blood culture systems.	BacT/Alert, BACTEC, VersaTREK, or Septi-Chek (biphasic) bottles. Isolator (lysis-centrifugation). RT, never refrigerate.
Bone marrow	Collect as per bacterial culture.	Collect in sterile container, Isolator, or heparin (green top) tube. If clotted, may have to homogenize or cut into pieces to place on mycology media. RT
CSF	Collect as per bacterial culture. Fluid volumes greater than 1 mL should be centrifuged or filtered.	Collect in sterile container. RT, never refrigerate. Always perform direct examination.
Eye	Corneal scrapings should be inoculated directly onto mycology media. Vitreous fluid should be collected by needle aspiration.	Direct inoculation onto mycology media without cycloheximide. Vitreous fluid can be placed in a sterile container, or the syringe with needle removed can be sent to the laboratory. RT.
Fluids other than CSF and urine	Collect as per bacterial culture. Fluid volumes greater than 1 mL should be centrifuged or filtered.	Collect in sterile container. RT. Always perform direct exam.
Hair	Use Wood lamp to help select infected hairs and obtain hair roots. Also scrape border of infected area if lesions are present.	Place 10–12 hair roots in sterile container. RT.
Nails	Swab surface with 70% alcohol. Clip nails or scrape with scalpel. Collect softened material from beneath nail bed.	Use sterile container or directly inoculate mycology media. RT.
Prostatic secretions	Empty bladder before giving prostate massage. For detection of <i>Blastomyces</i> and less commonly <i>Coccidioides</i> , <i>Cryptococcus</i> , and <i>Histoplasma</i> .	Place in sterile container or directly inoculate mycology plates. RT.
Respiratory	Collect as per bacterial culture using same rejection criteria for sputum. Early morning sputum is the preferred specimen.	Use sterile container. RT.
Skin	Disinfect surface area with 70% alcohol to remove bacterial contaminants. Scrape skin surface at the edge of the lesion or collect with soft-bristled toothbrush.	Use sterile container or directly inoculate mycology media. RT.
Tissue/biopsy	Collect specimen per surgical technique. Examine tissue for granules.	Use sterile container to which a small amount of sterile saline or water may be added to keep tissue moist. RT.
Urine	Collect as per bacterial culture. Early morning specimen is preferred. Use midstream collection technique.	Use sterile wide-mouthed container. RT.
Vaginal	Collect specimen as per bacterial culture. Primarily for <i>Candida</i> infections.	Swab transport device or sterile container. RT.

CSF, Cerebrospinal fluid; RT, room temperature.

the test may have to be validated by the laboratory before the results can be used clinically. β -D-Glucan is a major cell wall component of most fungi, with the exception of *Mucorales* and low amounts in *Cryptococcus* and *Blastomyces*. This serum antigen has been used as a diagnostic marker for invasive fungal infections. False-positive test results for β -D-glucan and galactomannan have occurred in patients exposed to specific bacteria and products containing these polysaccharides.

Molecular methods have found a successful rapid clinical diagnostic home for detecting fungemias (see Table 252.3). A number of laboratory-developed molecular tests for the detection of fungal pathogens using specimens other than blood are available in specialized centers, but none have been approved by the US Food and Drug Administration, although they may be approved for use in Europe.⁹

PRIMARY ISOLATION MEDIA

The most reliable and sensitive means for definitive diagnosis of a fungal infection is isolation of the organism on culture media.^{2,4,5} A variety of media are commercially available for primary isolation of fungal organisms (Table 252.4). The medium chosen should support the growth of fungal isolates while inhibiting bacterial organisms from specimens collected from nonsterile sites. Traditional antibiotics used include chloramphenicol, gentamicin, penicillin, and streptomycin. Antibacterial agents can inhibit actinomycetes; therefore media without antibiotics should be chosen if this agent is suspected, or a combination of media with and without antibiotics could be used.

Media may use cycloheximide, a protein synthesis inhibitor, to suppress the growth of saprophytic fungi. It also inhibits *Aspergillus*,

Candida, *Cryptococcus*, *Trichophyton*, and most *Mucorales* spp. Cycloheximide can be used in combination with various antibacterial agents listed earlier.

Chromogenic media are useful for the recovery and identification of *Candida* spp.⁴ Dermatophyte test medium (DTM) was designed specifically for the culture and isolation of dermatophytes. Other media used can be those containing caffeic acid for the detection of *C. neoformans* and *C. gattii* by its phenol oxidase activity or media overlaid with olive oil (long-chain fatty acid source) for the recovery of *Malassezia furfur*.

When processing tissue, avoid the use of a mortar and pestle or tissue grinder. Hyphal elements, particularly aseptate hyphae, are easily destroyed in this process, rendering culture recovery of *Mucorales* impossible. Recommendations are to mince the tissue with a scissors or scalpel blade into 1-mm cubes and to place these fragments onto the agar surface.

Nonselective media will permit the recovery of rapidly growing yeast and fungi as well as of fastidious, slow-growing fungi. Selective media will enhance the recovery of slower-growing dimorphic fungi while inhibiting the faster-growing yeast and fungi that may contaminate the medium and render isolation of the slower-growing organisms impossible.

In general, a battery of media, including media containing sheep blood (BHI and Sabouraud brain-heart infusion agar [SABHI]), is used for the recovery of fungal isolates. Although sheep blood inhibits conidiation, it does improve the recovery of fungal isolates. Agar plates or screw-capped tubes can be used for isolating fungal isolates. Most mycologists prefer agar plates because of the ease of handling the cultures, and the larger surface area provides for better isolation of colonies. Plates usually are

TABLE 252.2 Methods for Direct Microscopic Detection of Fungi in Human Specimens

Stain/Method	Use	Comments
Calcofluor white	Fluorochrome binds to chitin and cellulose in fungal cell wall.	Rapid detection of fungi and <i>Pneumocystis</i> . Staining time is 1 min; requires fluorescent microscope. Organisms fluoresce blue-white. May be used with Evans blue to suppress background fluorescence. Can be used with KOH to digest specimens.
Candida QuickFISH	Identifies three <i>Candida</i> spp. from blood culture broth.	Need fluorescent microscope and slide station. Expensive but 20 min to identify isolates.
Fontana-Masson	Detects <i>Cryptococcus</i> and dematiaceous fungi.	Stains melanin black or dark brown. Many nondematiaceous fungi will also stain.
Giemsa	Stains most bacteria and fungi.	Used for the detection of <i>Histoplasma</i> and <i>Talaromyces marneffei</i> in blood and bone marrow. <i>Pneumocystis</i> trophozoites and intracystic sporozoites can be detected. Organisms stain blue-purple.
Gridley	Stains fungal cell wall.	Cell wall stains purple-red with yellow background.
Gomori methenamine silver	Stains most organisms in tissue.	Fungi including <i>Pneumocystis</i> cysts stain gray-black. Difficult-to-control staining reaction and may be difficult to interpret because of background staining.
Gram	Is used primarily for detection of bacteria	Yeast cells and pseudohyphae stain gram positive; <i>Cryptococcus</i> stains gram positive surrounded by a capsular halo; hyphae will stain gram negative.
Hematoxylin and eosin	Is used to demonstrate nucleus and cytoplasmic inclusions in cells.	Fungi nucleus stain violet to blue-purple; cytoplasm stains pink. Can see fungal pigments.
India ink (Nigrosin)	Helps detect capsule of <i>Cryptococcus</i> , which appears as a clear halo around the organism. Capsule may be difficult to detect in some infections.	To help detect capsule of <i>Cryptococcus</i> capsule, which appears as a clear halo around the organism may be difficult to detect.
Mucin (Mayer or Southgate mucicarmine)	Stains mucopolysaccharide or fungal capsule.	Cryptococcal capsule stains red. <i>Blastomyces</i> and <i>Rhinosporidium</i> may also stain.
Papanicolaou	Is used to detect the presence of malignant cells.	Fungal elements stain pink. Some fungi may not stain.
Periodic acid–Schiff (PAS)	Stains glycogen, mucin, mucoproteins, and glycoprotein.	A mucin stain used to stain the capsular mucopolysaccharide of fungi. Capsule will have a pink-magenta or purple color.
Potassium hydroxide	Detects yeast and hyphal elements in wet mounts.	Used as a clearing agent to make fungi more visible in tissue, hair, nails, and body fluids. Digests proteinaceous material of host cells, leaving fungi intact.
Toluidine blue	Detects <i>Pneumocystis</i> cysts.	Cell wall stains purple.
Wright	Stains most bacteria and fungi.	Used for the detection of <i>Histoplasma</i> and <i>Talaromyces marneffei</i> in blood and bone marrow. <i>Pneumocystis</i> trophozoites and intracystic sporozoites can be detected. Organisms stain blue-purple.

BAL, Bronchial alveolar lavage or wash; CSF, cerebrospinal fluid; DFA, direct fluorescent antibody; EIA, enzyme immunoassay.

TABLE 252.3 Nonmicroscopic Direct Fungal Detection Methods

Organism	Specimen	Test	Comments
Antibody			
<i>Blastomyces</i>	Blood	CF, ID	X-rx with other dimorphic fungi
<i>Coccidioides</i>	Blood	CF, EIA, ID	Ab develop 4–6 wk after exposure; used to follow therapy
<i>Histoplasma</i>	Blood, CSF	CF, EIA, ID	X-rx with other dimorphic fungi
Antigen			
<i>Aspergillus</i>	Blood, BAL, CSF	Galactomannan	False-positive results with other filamentous fungi and bacteria
<i>Blastomyces</i>	Blood, CSF, urine	EIA	X-rx with other dimorphic fungi
<i>Coccidioides</i>	Blood, BAL, CSF, urine	EIA	X-rx with other dimorphic fungi
<i>Cryptococcus</i>	Blood, CSF, urine	EIA, LA, LFD	Highly sensitive and specific
<i>Histoplasma</i>	Blood, urine	EIA	X-rx with other dimorphic fungi
<i>Pneumocystis</i>	Blood, BAL	1,3- β -D-glucan	Lacks sensitivity and specificity
Molecular			
<i>Candida</i>	Blood culture broth	BCID (FilmArray)	5 species, 1 h, rapid ID but expensive
	Whole blood	T2Candida	5 species, 4 h, rapid ID, sensitive but expensive
	Whole blood or blood culture broth	Europe, LDT	Tests not approved by FDA
<i>Aspergillus</i>	Blood, BAL, CSF	Europe, LDT	Tests not approved by FDA
<i>Pneumocystis</i>	BAL	LDT	Tests not approved by FDA

Ab, Antibody; BAL, bronchial alveolar lavage; CF, complement fixation; CSF, cerebral spinal fluid; EIA, enzyme immunoassay; FDA, US Food and Drug Administration; ID, immunodiffusion; LDT, laboratory-developed test; LFD, lateral flow device; X-rx, cross-reacts.

TABLE 252.4 Primary Isolation Media

Media	Supplements	Use
CHROMagar, <i>Candida</i> or <i>Albicans</i> ID agar	Chromogenic substrates and antibiotics	Medium used for isolation and differentiation for recovery of clinically important yeasts. Assimilation of chromogenic substrates and colony color development allow presumptive identification of common <i>Candida</i> species. <i>Candida</i> spp. detected is manufacturer dependent.
Dermatophyte test medium	Chloramphenicol, cycloheximide, gentamicin	Selective and differential medium for recovery of dermatophytes (<i>Epidermophyton</i> , <i>Microsporum</i> , <i>Trichophyton</i>). Medium turns from yellow to red with growth of dermatophytes.
Inhibitory mold agar (IMA)	Chloramphenicol; gentamicin may be added	Selective and enriched medium used to isolate cycloheximide-sensitive fungi (<i>Candida</i> , <i>Cryptococcus</i> , <i>Histoplasma</i> , mucoraceous fungi, some <i>Aspergillus</i>) and inhibit bacterial growth.
Mycosel (Mycobioti)	Chloramphenicol and cycloheximide	Selective medium for isolation of dimorphic fungi and dermatophytes. Chloramphenicol inhibits bacterial growth, and cycloheximide inhibits rapidly growing molds and yeasts.
Potato flake agar	Can be made selective by addition of chloramphenicol and cycloheximide	Used to stimulate production of conidia and pigment.
Sabouraud brain-heart infusion agar (SABHI)	Used with (selective) or without antibiotics. Antibiotics include chloramphenicol, ciprofloxacin, cycloheximide, penicillin, and streptomycin. Could add sheep blood for recovery of <i>Histoplasma</i>	General-purpose medium for growth of most fungi, including yeast phase of dimorphic fungi.
Sabouraud dextrose agar (SDA)	None Addition of olive oil on surface	General-purpose medium supporting growth of aerobic actinomycetes and all fungi. Selective for cultivation of <i>Malassezia furfur</i> .
Yeast extract phosphate medium	Ammonium hydroxide and chloramphenicol	Selective medium promotes recovery of slow-growing dimorphic fungi. Chloramphenicol inhibits bacterial growth and ammonium hydroxide inhibits growth of other fungi.

sealed with air-permeable tape or shrink-wrap to prevent inadvertent opening of the plate and also to slow down or to retard dehydration of the media because many plates are held for 4 weeks in the laboratory before the specimen is signed out as negative. Examination of culture plates or agar tubes should be performed in a certified biologic safety cabinet. Most fungi will grow on routine bacteriology plates; however, the incubation time usually is short and may not allow sufficient time for the fungi to grow and be visually noticed on the plates.

Viral Laboratory Diagnosis

Romney M. Humphries • Marjorie J. Miller

In the past, diagnostic testing for viral agents consisted primarily of isolation of virus in tissue culture and serologic studies. These tests were often perceived as too impractical, nonproductive, and slow to warrant implementation in the hospital laboratory. Fortunately, technologic developments and an expanding commercial availability of reagents and test kits have enabled laboratories to provide effective virologic diagnostic services with turnaround time to results and charges similar to those for other areas of the microbiology laboratory. Although an increasing

number of these reagents are being approved or licensed as in vitro diagnostic devices, a major hurdle to implementing these in the laboratory is the requirement for laboratory verification of manufacturer-established performance characteristics for each test before implementation. Such verification studies often are extensive and taxing to laboratory resources, although manufacturers may offer educational and technical support to assist the laboratory, if permitted by local regulations. Practical guidance for verification studies has been published elsewhere.^{6,20,64}

Presently, virologic services offered by clinical laboratories may range from referral of specimens to a reference laboratory, to limited detection of viral antigens or nucleic acids or an extended menu of qualitative and quantitative molecular assays. This chapter presents the general aspects of diagnosis of viral infections, including specimen selection, collection, and transport; conventional and modified culture for virus isolation and identification; and rapid detection of viral antigens and nucleic acids directly in specimens. Specific aspects of diagnosis are presented in the respective chapters covering the viral agents.

SPECIMEN COLLECTION AND TRANSPORT

Laboratory diagnosis of viral infections depends primarily on the collection of appropriate specimens, in sufficient volume, at the correct time during the course of the illness using optimal transport and storage conditions. Improvements in the sensitivity and accuracy of laboratory assays will be rendered insignificant if preanalytic considerations are overlooked.

Specimen Collection Sites

The selection of appropriate specimens as early in the acute phase of the illness as possible is critical to the recovery of viruses. A guide to recommended collection sites for specific viral syndromes is presented in Table 253.1. In general, the extent of the diagnostic investigation should be dictated by the characteristics of the illness being studied. For example, in common respiratory illnesses such as pharyngitis or croup, collection of a single specimen from the throat usually is sufficient. In other situations in which an illness is severe or unique, collection of specimens from multiple sites is important. In addition, in unusual cases, serum should be obtained for frozen storage in case subsequent serologic studies are required.

In severe illnesses, invasive procedures (e.g., brain, cardiac, liver, lung biopsies, and needle aspiration of body fluids) frequently must be performed to obtain material for laboratory study. Many medical specialists argue against using these invasive procedures because little can be done to treat viral illnesses. However, in our experience, the knowledge gained from a positive viral identification justifies some risk incurred in collecting specimens. At present, antiviral drugs are similar to antibacterial and antifungal agents in that they generally can be used effectively only after definitive identification of the etiologic agent. Demonstration of a viral etiology in diseases such as encephalitis, pneumonia, or cardiac disease can prevent the unnecessary administration of antibiotics and steroids. In many cases, overuse of services, patient trauma, and overall cost can be reduced when a viral agent is confirmed. Finally, the prognosis of a particular illness is more accurate when the specific etiology is known.

Collection of Specimens

Specimens for virus culture or direct examination are generally obtained as they are for other microbiologic studies. The primary purpose of a transport medium is to provide a protective protein, neutral pH, and antibiotics for control of microbial contamination and, most important, prevention of desiccation. Many viral transport and storage media are available commercially. Saline or holding media that contain serum should be avoided. Useful liquid transport media (i.e., 2-mL aliquots in screw-capped vials) consist of tryptose phosphate broth with 0.5% bovine albumin; Hanks balanced salt solution with 5% gelatin or 10% bovine albumin; or buffered sucrose phosphate (0.2 mol/L, 2-SP), which has been used as a combined transport medium for viral, chlamydial, and mycoplasmal culture requests and is appropriate for long-term frozen storage of specimens and isolates. Many of these transport media also have been evaluated and found acceptable for use in rapid methods (e.g., enzyme-linked immunosorbent assay [ELISA] and nucleic acid amplification tests [NAATs]).¹⁵

Convenient and practical collection devices, such as UTM Kits (Copan), or Universal Viral Transport Kits (Becton Dickinson), consist of a swab, usually a nylon flocked swab on a plastic shaft, and a self-contained transport medium. Calcium alginate swabs, which are toxic to herpes simplex virus (HSV), and wooden shafts, which may be toxic to viruses and the cell culture system itself, should not be used. Nylon

flocked swabs should be used over traditional swabs whenever possible, because these are associated with both enhanced absorbance to, and subsequent release of, specimen from the swab.^{1,78}

Throat

Specimens from the throat should be obtained with a swab in a manner similar to that used for bacterial culture. The posterior pharyngeal wall and tonsillar surfaces, any inflamed or erythematous areas, and any visible lesions are swabbed firmly without contact with the tongue and anterior oral cavity.

Nose and Nasopharynx

Specimens should be collected with nasopharyngeal swabs that have thin, flexible shafts by inserting the swab into the nasopharynx and rotating it to obtain the maximal number of ciliated, columnar epithelial cells and then placing the swab in transport medium. Alternatively, nasopharyngeal secretions can be obtained from infants by nasal washing. In this method, a small amount of sterile phosphate-buffered saline (3–7 mL) is squeezed into the nose with a nasal bulb aspirator (1 oz, tapered) and then immediately withdrawn and placed in a sterile, screw-capped container. Nasopharyngeal aspirates also may be obtained with a mucus collection device. An appropriately sized catheter is inserted nasally into the posterior of the nasopharynx; intermittent suction is applied as the catheter is withdrawn. Aspirate is washed through the tubing with 5 to 8 mL of transport medium or sterile phosphate-buffered saline. Nasopharyngeal washes and aspirates should be placed into a viral-specific transport medium, which enhances sensitivity of both direct antigen tests and molecular methods. Although washes and aspirates were traditionally preferred for direct antigen detection, studies have shown equivalent collection of exfoliated virus-infected epithelia by flocked swabs. Nasopharyngeal specimens collected using flocked swabs yield sensitivity equivalent to that of aspirates for direct antigen detection and, in many cases, better sensitivity for NAATs.^{48,78} Generally, oropharyngeal and especially nasal specimens^{1,29} are thought to be of lower sensitivity than nasopharyngeal specimens, although some suggest collection of combined nasopharyngeal and oropharyngeal specimens for optimal sensitivity for respiratory virus detection by NAAT.^{29,36}

Other Respiratory Specimens (Sputum, Tracheal Aspirates, Bronchial Washings, Bronchoalveolar Lavage)

Collection depends on the volume obtained. Volumes of 0.5 mL or larger should be placed in a sterile container and sealed tightly. If the volume is less than 0.5 mL, the specimen is placed in 2 mL of transport medium.

Eye

Exudate or pus should be removed first with a sterile swab. Conjunctival specimens may be obtained by pressing a swab premoistened with sterile saline firmly against the inflamed areas. The swab is returned to the self-contained transport device. Corneal scrapings should be obtained by an ophthalmologist or other trained person and placed in transport medium immediately.

Body Fluids Other Than Blood

Body fluids such as urine (clean voided, 5–10 mL), cerebrospinal fluid (CSF) (2–5 mL), pleural effusion, and peritoneal, pericardial, or joint fluid should be collected under sterile conditions and placed in securely sealed, sterile containers. For small volumes (≤ 0.5 mL), the specimen may be placed in transport medium.

Lesions

For lesions, fresh vesicles should be selected because detection of virus decreases significantly as lesions age. They should be gently swabbed with sterile saline. The vesicle is ruptured and both fluid and cells collected from the base of the lesion. Material obtained from several lesions may be pooled. Desiccation must not be allowed to occur; swabs should be submitted moistened with their self-contained transport medium or, if that is unavailable, placed in 2 mL of transport medium. Specimens may be collected with a swab or aspirated with a 26-gauge needle attached to a tuberculin syringe. Aspirated fluid should be rinsed

TABLE 253.1 Specimen Collection Guide for the Diagnosis of Viral Infections Based on the Viral Syndrome and Etiologic Agent Suspected

Main Location or Category of Illness	Clinical Diagnosis	SPECIMEN COLLECTION SOURCE			Etiologic Agent Suspected ^a
		Most Practical	Most Definitive	Other Sources	
Upper respiratory tract	Common cold, nasopharyngitis	Nasopharynx	Nasopharynx	Nasopharyngeal/nasal, oropharyngeal swab, nasal swab, stool, blood	Rhinoviruses, coronaviruses, parainfluenza viruses, RSV, enteroviruses, adenoviruses
	Pharyngitis	Throat	Throat	Stool, blood	Adenoviruses, enteroviruses, Epstein-Barr virus, influenza viruses, parainfluenza viruses
	Herpangina, other enanthems	Throat	Lesions	Stool, blood	Enteroviruses, HSV
	Laryngitis, laryngotracheitis	Throat	Larynx or trachea	Nasopharyngeal/nasal wash	Parainfluenza viruses, influenza viruses
Lower respiratory tract	Parotitis, other salivary gland enlargement	Throat	Stensen duct	Urine, blood, cerebrospinal fluid	Mumps virus, enteroviruses
	Bronchitis, bronchiolitis, pneumonia	Nasopharynx	Bronchoalveolar lavage, bronchial washing biopsy	Blood, sputum, nasopharyngeal/nasal wash, stool	RSV, human metapneumovirus, parainfluenza viruses, adenoviruses, influenza viruses, cytomegalovirus
	Pleurodynia	Throat	Throat	Stool	Enteroviruses
	Pleural effusion	Pleural fluid	Pleural fluid	Throat, stool, blood	Enteroviruses, adenoviruses
Heart	Myocarditis, pericarditis, conduction defects	Throat	Pericardial fluid, biopsy	Stool, blood, urine	Enteroviruses, influenza viruses, adenoviruses
Central nervous system	Meningitis	Throat	Cerebrospinal fluid	Stool, blood, urine	Enteroviruses, mumps virus, arboviruses, HSV-2, lymphocytic choriomeningitis virus
	Encephalitis	Throat	Brain biopsy	Cerebrospinal fluid, stool, blood, urine	Arboviruses, mumps virus, enteroviruses, HSV-1, influenza viruses
	Guillain-Barré syndrome, cerebellar ataxia, transverse myelitis, poliomyelitis	Throat	Throat	Stool, blood, cerebrospinal fluid	Influenza viruses, arboviruses, enteroviruses, Epstein-Barr virus
Genital tract	Orchitis, epididymitis	Throat	Testicular biopsy	Stool, blood, urine	Mumps, enteroviruses, lymphocytic choriomeningitis virus
Urinary tract	Herpes genitalis	Lesions	Lesions	Vagina, cervix, urethra	HSV
	Cytomegalovirus infection	Urine	Urine	Throat, blood	Cytomegalovirus
Gastrointestinal tract	Hematuria and/or pyuria	Throat, urine	Urine	Blood, stool	Arboviruses, enteroviruses, mumps virus, adenoviruses, BK virus if immune compromised
	Nausea and/or vomiting	Throat	Throat	Stool, blood	Enteroviruses, influenza viruses, noroviruses
	Diarrhea	Stool	Stool	Throat	Rotaviruses, enteroviruses, adenoviruses, noroviruses
	Abdominal pain	Throat	Throat	Stool, blood	Enteroviruses, adenoviruses
	Acute abdomen	Throat	Mesenteric lymph node biopsy, peritoneal fluid	Stool, blood	Enteroviruses, adenoviruses
	adenitis	Throat	Liver biopsy	Stool, blood	Hepatitis A, B, C, E, and G viruses, Epstein-Barr virus, adenoviruses, enteroviruses, cytomegalovirus
	Hepatitis	Throat	Liver biopsy	Stool, blood	Enteroviruses
	Pancreatitis	Throat	Duodenal fluid	Stool, blood	Influenza viruses, varicella virus
	Reye syndrome	Throat	Liver biopsy	Blood	Adenoviruses, enteroviruses, Epstein-Barr virus, cytomegalovirus
	Hepatosplenomegaly	Throat	Blood, liver biopsy	Stool, urine	

Reticuloendothelial system	Generalized lymphadenopathy	Throat	Blood, lymph node biopsy Blood	Stool, urine Lymph nodes	Adenoviruses, enteroviruses, Epstein-Barr virus, cytomegalovirus HIV
Bone or joints	Immunodeficiency	Blood	Blood		
	Osteomyelitis	Bone	Bone	Throat, blood, urine, skin lesion	Rubella virus, vaccinia virus
	Arthritis	Joint fluid	Joint fluid	Throat, blood, urine	Rubella virus, arboviruses
Muscle	Myositis	Throat	Muscle biopsy	Stool, blood	Influenza virus, enteroviruses
Skin	Exanthematous disease	Throat	Vesicular fluid, skin biopsy	Stool, blood, urine, eye	Measles virus, rubella virus, varicella virus, enteroviruses, HSV
Eye	Conjunctivitis, including pharyngoconjunctival fever	Conjunctiva	Conjunctiva	Throat, stool	Adenoviruses, enteroviruses
Eye	Keratoconjunctivitis	Conjunctiva, cornea	Conjunctiva, cornea	Throat, stool	Adenoviruses, herpes simplex virus, varicella virus
	Retinitis	Vitreous, aqueous fluid	Vitreous, aqueous fluid		Cytomegalovirus, herpes simplex virus, varicella virus
Fever	Nonspecific febrile illness (human-to-human transmission)	Throat	Blood	Stool, urine, cerebrospinal fluid	Enteroviruses, influenza viruses, adenoviruses, cytomegalovirus
	Nonspecific febrile illness (arthropod vector)	Blood	Blood	Throat, urine, cerebrospinal fluid	Arboviruses
	Fever of unknown origin	Blood	Blood	Urine, stool, throat	Hepatitis A, B, C, E, and G viruses, cytomegalovirus, herpes simplex virus, Epstein-Barr virus, adenoviruses
Congenital infection	Rubella virus Cytomegalovirus infections Zika virus	Throat Urine, saliva Urine, blood	Blood Urine (first 21 days life) Urine, blood (first 48 hours life)	Nasopharynx, biopsy material, cerebrospinal fluid, lens of eye	Rubella virus, cytomegalovirus, Zika virus
	HIV infection	Blood	Blood	Lymph node	HIV
Perinatal and neonatal infections	Herpes simplex virus, cytomegalovirus, enterovirus infections	Throat, urine	Blood	Urine, nasopharynx, stool, skin lesions, cerebrospinal fluid	Enteroviruses, RSV, influenza viruses, herpes simplex virus, cytomegalovirus

*This list includes only the more commonly associated agents. It is likely that with more general use of viral diagnostic services, new virus and disease associations will be made.
HIV, Human immunodeficiency virus; HSV, herpes simplex virus; RSV, respiratory syncytial virus.

into 1 to 2 mL of transport medium. Syringes should not be submitted to the laboratory with the needle attached.

For direct antigen detection by immunofluorescence (direct fluorescent antibody [DFA]), the vesicle is ruptured as previously described and epithelial cells are collected by firmly swabbing the base of the lesion. Cells are transferred to a clean glass slide by firmly rolling the swab back and forth over a 5- to 10-mm area (dime size) or, if a ringed slide is used, into the center of the ring. For differentiation of HSV types 1 and 2 (HSV-1 and HSV-2) and varicella-zoster virus (VZV) by DFA, three slides should be prepared.

Stool and Rectal Specimens

Fecal specimens should be collected only when the specific primary diagnosis is diarrhea or when concomitant serologic study with paired sera can be performed. Both enteroviruses and adenoviruses can be detected and recovered readily from stool, but because these agents are carried in the lower gastrointestinal tract for considerable periods of time after acute infection, use of this source for establishing the diagnosis of specific illnesses is limited.

For recovery of enteroviruses, fresh stool specimens are better than rectal swabs; 2 to 5 g (2–3 tsp) of formed or liquid specimen should be transferred to a sterile, leak-proof container. However, from a practical point of view, a rectal swab is the simplest method of specimen collection. A rectal swab can be obtained immediately, whereas collection of a stool specimen usually entails considerable delay. Of importance is that the swab contain visible stool; the swab should be inserted 3 to 5 cm into the rectum, rolled against the mucosa, and then transported in transport medium.

Blood

Some viruses can be recovered from serum or red blood cells (RBCs), but in general, leukocytes are a better source of virus. Fresh blood (optimally 5 mL) is collected in a suitable anticoagulant (i.e., heparin, ethylenediaminetetraacetic acid [EDTA], or acid citrate dextrose) and transported to the laboratory for processing to enrich for leukocytes. EDTA is the anticoagulant of choice because it is an acceptable transport for culture, as well as for molecular methods such as hybridization and PCR.

Bone Marrow

Approximately 2 mL should be aspirated into a tube or syringe containing heparin anticoagulant, mixed thoroughly to prevent clotting, and transported without further additives or diluents.

Biopsy Specimens

For biopsy specimens, fresh tissue obtained from the affected site should be placed in 2 mL of transport medium to prevent desiccation.

Autopsy Specimens

Most postmortem specimens are almost useless for viral cultivation because of the manner in which autopsies usually are performed. If labile agents are to be recovered, the autopsy should be performed within 4 hours of death. All tissues (as 1- to 2.5-cm cubes) for study should be obtained aseptically, and individual tissue should be collected with sterile instruments and placed in separate sterile containers. Because the usual autopsy routine entails fixation of specimens, of vital importance is that specimens for viral isolation not be placed in containers with fixatives such as formalin or other preservatives.

Transport to the Laboratory

The method of handling specimens from the time of collection to laboratory processing is critical not only for preservation of virus infectivity for recovery in culture but also for optimal preservation of nucleic acid integrity before molecular detection methods. In general, the less time that transpires between collection and processing by the laboratory, the greater is the chance of detecting the virus. Specimens should not be frozen or exposed to temperatures higher than 22°C (71.6°F). For short-term storage (<5 days) of most viruses, the specimen should be held at 4°C (39.2°F) until it can be processed in the laboratory. For transport to the laboratory, this temperature can be achieved with

the use of cold packs or ice. Transport of specimens at 4°C is less critical for testing by molecular-based assays, provided an appropriate transport medium is used and the delay is not greater than 1 day.¹⁵

When considerable delay between collection and culture will elapse (e.g., transport to other laboratories, holiday schedules, and so on), special preparation is necessary. Such preparation needs to be individualized and based on the most likely viral cause of a particular illness. For example, when an enteroviral etiologic agent is suspected, freezing the specimen (–70°C [–94°F]) and shipping it with dry ice are satisfactory. In contrast, a urine specimen from a patient with possible cytomegalovirus (CMV) infection should not be frozen. It should be shipped under wet ice at 4°C (39.2°F) because CMV in urine is stable for several days at this temperature. For specific characteristics of individual viruses, see the respective chapters in this book.

LABORATORY DIAGNOSIS OF VIRAL INFECTIONS

In recent years, technologic advances have provided powerful and achievable methods for the detection of viruses in clinical specimens. Widespread availability of commercial reagents and kits for molecular detection and quantitation of viral nucleic acids in specimens has made these methods accessible for many hospitals. In some instances, qualitative NAATs can be performed in the clinic, at the point of care. Laboratories may combine both culture and nonculture approaches to optimize viral disease diagnosis, although most have eliminated culture in deference to the superior sensitivity, specificity, and turnaround times achievable by molecular methods. [Table 253.2](#) summarizes optimal methods for the laboratory identification of specific viruses, and more in depth information is presented in the individual chapters of this book.

Virus Isolation

Isolation of viruses in culture is no longer routinely performed by many clinical laboratories but remains available in many reference and public health laboratories. Unlike rapid methods, which are limited to the detection of specific viral antigens or nucleic acids, culture is open-ended and permits detection of unexpected or new viruses. In addition, a broad range of specimens can be evaluated by culture, whereas more rapid methods are licensed for use with a defined and limited number of specimens. Viruses that can be isolated in culture and readily identified include adenoviruses, HSV, VZV, CMV, enteroviruses, rhinoviruses, influenza and parainfluenza viruses, respiratory syncytial virus (RSV), rubella virus, mumps virus, and measles virus. For optimal laboratory diagnosis, indicating the name of the suspected virus on the requisition is important because some viruses require specific cell lines, procedures for identification, or both. Cultures are maintained for different time frames before finalizing a report of negative results, depending on the virus being sought. For example, HSV cultures usually are observed for 5 to 7 days, CMV for 1 month, and all others for 2 to 4 weeks.

Traditional Culture

For traditional culture, clinical samples are inoculated onto one or more cell lines, selected based on the submitted specimen and suspected virus. Cultures are observed at regular intervals for evidence of viral infection characterized by the appearance of cytopathic effect, the ability to hemadsorb or hemagglutinate RBCs, or immunofluorescence with monoclonal antibodies. Adenoviruses, CMV, HSV, VZV, rhinoviruses, and enteroviruses can be identified and reported by their characteristic cytopathic effect. Parainfluenza and influenza viruses, in contrast, may or may not produce cytopathic effect but can be detected with the traditional hemadsorption method, in which a suspension of guinea pig RBCs is added to the cell culture. The RBCs adhere to tissue culture cells infected with these viruses. RSV is identified presumptively by its typical cytopathic effect (syncytium formation) and definitively by immunofluorescence with monoclonal antibodies. The traditional method for isolation and identification of rubella virus is by evaluating for interference of the cytopathic effect of a second virus, usually echovirus 11. Finally, although rarely performed, definitive identification of viral serotypes (e.g., adenovirus and enterovirus) by the neutralization test can be done for epidemiologic purposes. For the most part, the

TABLE 253.2 Common Laboratory Methods for Diagnosis of Specific Viral Illnesses^a

Virus	Culture	Antigen Detection	Serology	Nucleic Acid Amplification Test	Most Useful Method for Diagnosis
Adenoviruses	Not routine	DFA ELISA	Reference or public health laboratory	Detected by some multiplexed respiratory virus NAATs Single-analyte commercial NAAT available	NAAT

neutralization test has been replaced by nucleic acid sequencing approaches to serotyping, which have equivalent specificities.^{43,51}

NAATs, serologic tests, or a combination of the two are recommended for viruses that are difficult or impossible to isolate in commonly employed cell lines or that require special techniques for detection of their presence. For instance, although mumps virus can be isolated in the same cell lines used for other paramyxoviruses and detected by hemadsorption or hemagglutination, NAAT and serology are preferred methods for establishing diagnosis. Buccal or oral swabs collected early in disease are tested by reverse transcriptase polymerase chain reaction (RT-PCR) assay for mumps virus. If negative, acute and convalescent serum specimens may reveal diagnosis in patients with signs and symptoms of mumps. Similarly, when measles is suspected, diagnosis is confirmed most easily by serologic studies or NAAT. Paired sera collected 1 week apart usually reveal a fourfold antibody titer rise. Alternatively, demonstration of a single measles-specific immunoglobulin M antibody or detection of measles RNA by RT-PCR performed on oropharyngeal or nasopharyngeal swabs or urine establishes diagnosis. It should be noted that specimens for NAAT should be collected no more than 3 days after onset of rash, although RNA may be detected as late as 14 days after rash onset.

Modified Culture

Several physical and chemical methods enhance the detection of virus in culture. One common technique, termed the shell vial assay (SVA), entails centrifugation of the specimen onto a cell monolayer and detection of early antigen. This method is used by most laboratories that continue to perform viral cultures because it significantly decreases the time to result (i.e., 1–3 days) compared with traditional culture (5–30 days). Antigen is detected by immunofluorescence or occasionally by immunoperoxidase staining with monoclonal antibodies directed against a specific virus, before the appearance of cytopathic effect. SVAs are used extensively for detection of HSV, CMV, VZV, adenovirus, RSV, influenza virus, parainfluenza virus, measles virus, and human metapneumovirus.

Pooled antibodies directed against seven commonly isolated respiratory viruses (i.e., adenovirus; influenza viruses A and B; parainfluenza virus types 1, 2, and 3; and RSV) are commercially available.^{46,55,63} To be adequately sensitive for each of these respiratory viruses, either two or more single cell lines in shell vial are used or mixed cell lines are applied to shell vial cultures. The commercially available R-Mix (Diagnostic Hybrids) mixed cell line, for example, consists of one cell line to support replication of RSV, adenovirus, and parainfluenza (i.e., A549) and another to support replication of influenza (i.e., Mv1Lu). R-Mix Too was developed after recognition that severe acute respiratory syndrome–coronavirus (SARS-CoV) readily infected Mv1Lu cell lines²³; R-Mix Too mitigates the risk for inadvertent amplification of SARS-CoV in the routine clinical laboratory by replacing Mv1Lu with MDCK cell lines.

A second modification of cell culture is for the rapid detection of HSV using an enzyme-linked virus-inducible system (ELVIS).⁷¹ This system consists of a mixture of modified baby hamster kidney cells and MRC-5 cells. The modified baby hamster kidney cells contain an HSV-inducible promoter and an *Escherichia coli* LacZ reporter gene that produces β -galactosidase only when cells are infected with HSV. After the addition of a substrate for the β -galactosidase, infected cells stain blue, whereas uninfected cells remain colorless. ELVIS appears to be comparable to culture for the detection of HSV-positive specimens (95% and 100% sensitivity) in a similar time frame, 1.4 to 1.7 days.⁴⁵

Direct Detection

Cytology

Historically, rapid detection of viral infection relied on light microscopy and evaluation of tissues and exfoliated cells for viral inclusions or other cytopathic effects. Cytologic identification of virus is most useful in illnesses with vesicular exanthems such as HSV or VZV infection. A scraping of the base of an HSV or VZV lesion (Tzanck smear) reveals multinucleated giant and balloon cells when stained with hematoxylin and eosin, Wright, or Giemsa stain. In contrast, vesicular lesions caused by enteroviral infections do not contain giant or balloon cells, and allergy-related lesions contain eosinophils. Cytologic study of urine in

congenital CMV infection reveals cells with the characteristic “owl’s eye” intranuclear inclusions in 25% to 50% of cases, and nasal or pharyngeal smears in measles may reveal typical giant cells. These types of stains are no longer routinely performed in most diagnostic virology laboratories because they have been replaced by immunofluorescence or NAATs, which are more sensitive and specific. Whereas the Tzanck smear cannot differentiate HSV from VZV and the presence of multinucleated giant cells is necessary to make the diagnosis, immunofluorescence can identify the causative agent specifically, and the presence of viral antigen in balloon or giant cells is diagnostic.

Antigen Detection

Antigen-detection methods are available for most commonly isolated viruses. Advantages of these methods include speed, standardized reagents and kits, the ability to detect nonviable, nonculturable, or difficult-to-grow viruses, and the ability to detect antigen when culture may be negative late in the course of infection. Generally, these methods are not as sensitive as NAAT or an optimized culture; thus NAAT or culture backup is recommended. DFA, indirect immunofluorescent assay (IFA), and ELISA, as well as lateral flow immunoassay platforms, are used most commonly for antigen detection in the clinical laboratory.

Immunofluorescence

Antigen detection by immunofluorescence requires collection of the appropriate cell types (i.e., those in which the virus propagates) in adequate numbers for evaluation. In some cases, the specimen is placed on the slide directly (e.g., HSV or VZV detection), but usually the sample is transported to the laboratory for processing and slide preparation (e.g., for respiratory virus detection). As is the case for all methods discussed in this chapter, the importance of adequate specimen collection cannot be overemphasized. When stringent specimen quality criteria are applied (e.g., ≥ 60 columnar epithelial cells per sample for influenza testing), DFA sensitivity approaches that of NAATs.⁶¹ However, such adequate specimens are infrequently collected, even when staff are trained in proper collection techniques.⁴²

DFA methods use virus-specific monoclonal antibody labeled with fluorescein dye to detect antigen and usually require approximately 30 to 45 minutes to complete. If processing of the specimen is required and slides are prepared in the laboratory, additional time is necessary. For IFA, unlabeled monoclonal antibody is added to the sample and incubated, followed by a wash and the addition of fluorescein-labeled antihuman immunoglobulin. After an additional incubation and wash, the slide can be examined for typical fluorescence. IFA can be completed in 2 to 3 hours. The advantage of using DFA or IFA is the ability to determine specimen adequacy and to perform small-batch and demand testing. A high-quality microscope and skilled, experienced personnel are required for optimal preparation and evaluation of the specimen.

The first DFA reagent available for use in the diagnostic laboratory was for the detection of HSV in genital, dermal, oral, and anal lesions. The test should not be used for detection of HSV in CSF, asymptomatic genital specimens, tracheal aspirates, or bronchoalveolar lavage (BAL) specimens. Sensitivity of the DFA (and culture) for HSV detection varies by the stage of the lesion. DFA or culture detected HSV in 96.7% of vesicles, 79.2% of pustules, 44.7% of ulcers, and 16.7% of crusts.³⁹ In contrast, detection of HSV by NAAT is less influenced by lesion stage¹⁹ and may increase yield of a positive result by 13% of vesicles, 28% of ulcers, and 20% of crusts.⁶⁸ Nonetheless, lesion duration and morphology remain strongly associated with the likelihood of HSV detection by NAAT, and negative results were obtained in 41.4% of vesicles, 48.4% of ulcers, and 76.9% of crusts.

DFA was also used historically for detection of VZV and remains a reliable test for primary disease in unvaccinated individuals. However, the utility of DFA for detecting VZV in the post–varicella vaccine era is diminished by the fact that breakthrough disease in previously vaccinated patients presents as a macular or papular rash, from which virus-infected cells for DFA testing cannot be readily collected. In such instances, NAAT should be performed on a swab or scraping of the rash, which is associated with 95% to 100% sensitivity.^{42,79}

Detection of CMV antigen in lung tissue or BAL specimens and in liver tissue has been used for diagnosis of CMV pneumonia or hepatitis.

However, the sensitivity of DFA is less than that of CMV culture, SVA, or NAAT. The preferred specimen for diagnosis of CMV pneumonia by DFA is a lung biopsy, although BAL specimens are collected far more commonly. A comparison of the cellular portion, supernate, and whole BAL for isolation of CMV in culture suggested that CMV is associated with the cell-free rather than the cellular component.¹⁰ The pp65 antigenemia assay consists of separation of leukocytes from whole blood, spotting or cytocentrifuging cells onto microscope slides, fixation and permeabilization, staining with anti-pp65 monoclonal antibodies, and detection by fluorescein-labeled or peroxidase-labeled secondary antibodies. pp65-Positive leukocytes are quantitated. This assay has widely been replaced in clinical practice by CMV DNA qualitative and quantitative PCR. The main limitation of the pp65 antigenemia assay is that it can only be performed on blood, whereas NAATs have been validated on several specimen types.

Finally, DFA and IFA are useful for the rapid detection of common respiratory virus in nasopharyngeal washes, aspirates, and suction. DFA for RSV has been evaluated extensively. As is the case for VZV, RSV is relatively labile, and antigen detection actually may be more sensitive than culture. However, the DFA is less sensitive than NAAT, detecting only 73.9% of NAAT-positive cases in one study.⁴⁰ In addition, because up to 30% of specimens submitted for establishing the diagnosis of RSV contain other viruses,^{5,9} multiplex NAATs or DFAs that evaluate for other respiratory viruses may be advisable when evaluating the patient with respiratory tract infection. The sensitivity of DFA and IFA for detection of influenza virus A and B, parainfluenza virus 1, 2, and 3, and adenovirus antigens varies, so NAATs must be performed if these are negative, for optimal diagnosis.

Enzyme-Linked Immunosorbent Assays

Standardized, well-characterized commercial kits for the detection of viral antigen by ELISA are available for HSV, RSV, influenza virus A and B, rotavirus, norovirus, adenovirus, HIV (p24), human T-lymphotropic virus (HTLV) 1 and 2, and hepatitis B virus (HBV). Intracellular and extracellular antigen can be detected; the methods are generally simple technically and are less affected by suboptimal specimen handling than are viral cultures. ELISAs come in two basic formats, either a classical microtiter or self-contained rapid immunochromatographic tests (RICT). The microtiter format uses antibodies lining the surface of the solid phase to capture viral antigen, which in turn is reacted with an enzyme-labeled secondary antibody, followed by detection with the addition of substrate and color development. Results are read spectrophotometrically and thus are objective, thereby eliminating some of the difficulties inherent in microscopic techniques, which require technical skill and expertise for evaluation of specimens. A major limitation of these approaches compared with DFA is that the adequacy of the specimen cannot be ascertained.

RICTs use a membrane as the solid support to retain viral antigen, to which enzyme-labeled antibodies are added to react with trapped antigen. Antigen-antibody complexes are detected using a chromogenic substrate, which is read visually. Although they are rapid (15–20 minutes) and simple to perform, RICTs tests are more expensive, require more hands-on time, and do not result in objective end points. False-positive results and interpretation can be a problem. Some membrane-based methods use analyzer reader devices to standardize result interpretation, which have been shown to improve sensitivity and specificity of these assays.¹⁶ Detection of influenza and RSV antigens in nasopharyngeal aspirates, washes, suction, and swabs has been evaluated extensively in standard and membrane ELISA formats.

Many of the RICTs are Clinical Laboratory Improvement Amendments (CLIA) waived, meaning they may be performed in emergency departments, outpatient clinics, and physician offices for point-of-care diagnosis of influenza A and B and RSV in patients with compatible respiratory symptoms. The clinical performance of these RICTs may vary significantly from the specifications listed in the package insert and year to year based on circulating virus type and subtype. Similarly, these tests have limited sensitivity compared with NAATs, and negative results should be interpreted with caution, in particular during peak influenza season, and should be backed up by NAAT. For instance, the sensitivity of the BinaxNOW Influenza A & B was 75% for influenza A virus and 72%

for influenza B during one influenza season, but only 48.9% and 36%, respectively, for a subsequent season, because of antigenic drift in the seasonal influenza virus.²⁴ Similarly, the reported sensitivity of various RICTs to detect novel influenza viruses, such as the 2009 (H1N1) pandemic and the H3N2v 2012 influenza strains, was 0% to 70%,^{17,18} depending on test manufacturer. The performance of RICTs also depends on the prevalence of the virus among patients with febrile respiratory tract infections. When the prevalence of influenza in children with compatible symptoms was 5%, the predictive value of a positive RICT was found to be 50% in contrast to RT-PCR and the predictive value of a negative test to be 98%.²⁵ Conversely, when the prevalence of influenza was 21%, the positive predictive value was 85% and the negative predictive value was 91%.²⁵ Finally, performance of the RICTs decreases as time from onset of symptoms increases. Thus, for optimal diagnosis, these should be used when disease prevalence is high and in patients with 4 days or less of symptoms. The Centers for Disease Control and Prevention in the United States also reports annually on the availability of these tests; these data are available at http://www.cdc.gov/flu/professionals/diagnosis/clinician_guidance_ridt.htm.

Children shed high titers of RSV; therefore RICTs for RSV performs significantly better in the pediatric population than do influenza tests. However, optimal performance is based on patient age and timing of specimen collection relative to onset of symptoms. The BinaxNOW RSV was positive in 79% to 91% of children younger than 1 year of age in contrast to NAAT-confirmed or culture-confirmed RSV infection, but in only 52% of those 1 year of age and older⁴⁷ to 25% of adults.⁵⁴ The assay was positive in 92% of patients with 0 to 1 day of symptoms, 78% with 2 to 4 days, and 65% with 5 or more days of symptoms.⁴⁷ Similar to influenza, performance of RSV RICTs varies significantly year to year and with virus prevalence.¹²

Rotavirus antigen detection by standard ELISA has been studied thoroughly. Many of the assays have excellent sensitivity (93–100%) and specificity (98–100%) in contrast to that of electron microscopy. Detection of rotavirus by ELISA may be preferred over more sensitive methods, such as RT-PCR. In one study of 648 children with acute gastroenteritis and 500 healthy controls, ELISA was found to have higher clinical specificity for rotavirus than was RT-PCR. Although more rotavirus was detected in both cases and controls by the RT-PCR, these were at low viral loads and in children who had been vaccinated against rotavirus, suggesting rotavirus was not the cause of gastroenteritis in the symptomatic children.⁷⁴ RICTs also are available for rotavirus antigen detection and, as is typical of this format, are somewhat less sensitive than standard ELISA, with approximately 10⁷ virions/mL required for detection of a positive specimen. An excellent ELISA for detection of adenovirus 40 and 41 in stool specimens is available and yields a reported sensitivity and specificity of 96%.^{33,80}

Nucleic Acid Detection

Molecular methods for the detection, identification, and characterization of microorganisms are being adapted increasingly for use in the clinical laboratory. These assays provide a timely and specific diagnosis, although the cost of reagents can range from \$30 to more than \$200 per test. NAATs were first developed in-house primarily for the identification of viruses that are not readily cultured (e.g., HSV from CSF) and for those in which time to detection by traditional means is too long to affect patient care (e.g., CMV). The past several years have witnessed an explosion in the number of NAATs for the rapid detection of all viruses commonly encountered in clinical practice, including many that are cleared by the US Food and Drug Administration (FDA) as in vitro diagnostic devices. When all costs are accounted for, including length of stay, frequency of diagnostic testing, and antibiotic use, diagnosis of respiratory viruses in children by a multiplex molecular method has been shown to be associated with cost savings equaling the cost of the assay or higher.⁴⁴

Increased use of molecular testing for the diagnosis of viral infections has stimulated several recent developments, including automation of nucleic acid extraction, amplification, detection, and reporting and interpretation of results. Several “sample to answer” platforms are now commercially available, allowing use of these technologies in smaller laboratories situated in community hospitals or emergency departments

that do not have expertise in sophisticated molecular diagnostics, although careful application of techniques to avoid nucleic acid cross-contamination is required. Recently, several commercial, CLIA-waived cartridge-based NAATs have come to the market, enabling rapid, point-of-care testing in the clinic.

In most cases, NAATs offer enhanced sensitivity and specificity over the other assays described in this chapter. However, clinical specimens sometimes contain inhibiting substances that interfere with the performance of NAATs. Internal control nucleic acids, generally in the form of bacteriophages or murine viruses, may be spiked into clinical specimens to monitor for inhibition. Additional limitations of NAATs are the potential for sample to sample or amplicon cross-contamination, leading to false-positive results and the inability to distinguish between actively replicating virus and residual viral nucleic acids. Similarly, because NAATs are significantly more sensitive than traditional methods, it is becoming apparent that some populations may be colonized with low levels of virus that are undetectable by culture or antigen based testing.⁷⁴

NAATs approved or cleared by the FDA at the time of writing are discussed in the following sections with respect to their application for the diagnosis and monitoring of certain viral infections. The analytical and clinical performance characteristics of these tests are well defined, and these assays undergo routine quality assurance monitoring. Because the list of FDA-approved/cleared molecular assays is ever expanding, readers are directed to the FDA website (<http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiagnostics/ucm330711.htm>) for

a comprehensive up-to-date list of FDA-approved/cleared tests. In addition, laboratories may develop NAATs through use of analyte-specific reagents that are widely available for a variety of viral targets. These laboratory-developed tests can then be validated for clinical use in accordance with CLIA requirements, which must include assessment of accuracy or bias, precision, linearity, limit of detection, interfering substances, and stability. The sensitivity and specificities of these laboratory-developed assays will vary across laboratories, and thus results from different laboratories cannot be used for comparison.

CLIA-Waived Nucleic Acid Amplification Tests

Recently, two CLIA-waived NAATs were cleared by the FDA for the detection of influenza (Table 253.3). The Alere i Influenza A & B assay is performed on nasopharyngeal swabs and uses a nicking endonuclease amplification reaction for ultrarapid amplification of DNA or RNA, which is detected by fluorescently labeled molecular beacons. The assay yields results within 15 minutes, with all steps performed onboard the Alere platform.⁵⁰ The Cobas Liat system similarly detects influenza A and B nucleic acids within 20 minutes, by Taqman probe-based RT-PCR.⁹ Both systems are rapid to perform in the clinic, requiring less than 3 minutes hands-on time to prepare testing. Early data suggest the Alere i Influenza A & B assay may be less sensitive than conventional PCR performed in the laboratory, with sensitivity ranging from 77.8% for influenza A to 75% for influenza B.³² Nonetheless, sensitivity was significantly improved over rapid ELISA tests performed in the clinic,

CLIA, Clinical Laboratory Improvement Amendments; CSF, cerebrospinal fluid; HCV, hepatitis C; hMPV, human metapneumovirus; HSV, herpes simplex virus; NAAT, nucleic acid amplification test; RSV, respiratory syncytial virus; RT-PCR, reverse transcriptase polymerase chain reaction; VZV, varicella-zoster virus.

which were only 25% to 71.4% sensitive for influenza A and B. In contrast, the Liat system was shown to have sensitivity of 99.2% for influenza A and 100% for influenza B in one early study.⁴

Single-Analyte Nucleic Acid Amplification Tests

Many single-analyte NAATs are available for detection of viruses in clinical specimens (see Table 253.3). NAATs have become the gold standard test for many viral infections. For example, NAATs on CSF are the procedure of choice for diagnosis of HSV encephalitis, although at the present, only one singleplex assay, the Simplexa HSV 1 & 2 Direct, has been cleared by the FDA for this indication (see Table 253.3). Several commercial HSV NAATs (see Table 253.3) are cleared for testing of cutaneous and mucocutaneous lesions. These assays detect and differentiate HSV-1 and HSV-2 and are associated with enhanced sensitivity in contrast to culture. NAATs are able to identify asymptomatic HSV, detect the presence of HSV for a longer period (in older lesions and even fixed tissue), and have greater diagnostic value than culture and clinical observations for assessing genital HSV and treatment efficacy in patients with recurrent genital HSV.^{31,49}

Similar to HSV, detection of enterovirus in CSF by NAAT is the standard, because of slow growth or failure of certain serotypes to grow in culture. The sensitivity of the commercial enterovirus NAATs is 83% to 100%, whereas culture of CSF yields an isolate in only 36% of patients with enteroviral meningitis.⁵² Such assays are particularly helpful because CSF evaluation for pleocytosis is not always reliable for diagnosis of enteroviral meningitis.⁶⁷ The Xpert EV is the only FDA-cleared assay for this indication. It is a cartridge-based assay designed to be run on demand, in emergency departments, yielding results in a time frame suitable for making medical management decisions.

Single-analyte, commercial NAATs are also available for the qualitative detection of adenovirus, hepatitis C virus (HCV), norovirus, and Zika virus from a variety of specimens (see Table 253.3). Many laboratory-developed tests are commonly available at both reference and hospital laboratories for other viral agents.

Multiplexed Assays

Multiplexed assays for the detection of influenza A and influenza B are listed in Table 253.3. These assays replace DFA and rapid antigen tests

as a sensitive and specific means by which to rapidly detect these viruses. Several of these assays have the added benefits of also detecting RSV and providing a differentiation between the influenza A virus subtypes. All of the assays described in this section have excellent performance, with published sensitivities and specificities of more than 95% for their specific targets, when performed per manufacturer instructions.

The Prodesse ProFAST+ (Hologic) assays are multiplex real-time RT-PCR for the qualitative detection and discrimination of seasonal influenza A/H1, A/H3, and 2009 H1N1 viral nucleic acids. The assay targets the hemagglutinin gene and does not detect influenza B or C. In contrast, the Prodesse ProFlu+ (Hologic) assay targets the matrix gene for influenza A, the nonstructural genes NS-1 and NS-2 from influenza B, and the polymerase gene of RSV A and RSV B. In both assays, specimen is processed on an off-line nucleic acid extractor, and NAAT is performed on a Cepheid SmartCycler II instrument. The assay is based on Taqman chemistry, in which a target-specific probe with a 5' fluorophore and a 3' fluorescence resonance energy transfer (FRET) quencher anneals to the viral cDNA. While the probe is intact, fluorescence is quenched by FRET by the quencher molecule. However, during DNA amplification, the 5' to 3' exonuclease activity of Taq DNA polymerase cleaves the fluorophore from the probe, displacing it from the quencher, and allowing fluorescence. Assays for the detection of adenovirus (ProAdeno+), and parainfluenza (ProParaflu+) are also available from the Hologic Prodesse line of assays. Like the Prodesse assays, the Quidel Lyra Influenza A + B assay uses Taqman chemistry for the detection of influenza A and B. The Lyra assays also multiplexed assays for HSV-1, HSV-2, and VZV from lesions, human metapneumovirus and RSV from throat swabs, and parainfluenza 1, parainfluenza 2, and parainfluenza 3 from nasopharyngeal swabs.

The Simplexa assays (DiaSorin) are performed on the 3M integrated cyclor instrument. These assays are either performed direct from specimen (e.g., FluA/B & RSV Direct) or following off-line nucleic acid extraction (e.g., FluA/B & RSV). In these assays, RT-PCR is detected through use of bifunctional scorpion primer/probe molecules in which the 5' end of the primer is covalently linked to the probe. The probe is a self-complementary stem sequence with a fluorophore at one end and a quencher at the other. When the probe anneals to the amplicon, the fluorophore and quencher separate, leading to an increase in fluorescence. Sensitivity of the Simplexa Flu A/B & RSV Direct assay was reported for influenza A as 82% to 96%, for influenza B as 76% to 99%, and for RSV as 95% to 98%.⁴⁰ Specificity is greater than 99% for all three targets. Finally, the Cepheid Xpert Flu is a cartridge-based assay that uses real-time PCR with molecular beacon detection and is performed on the GeneXpert instrument. Molecular beacon probes that have self-complementary ends that form a stem-loop structure in their native state, keeping a 5' fluorophore and a 3' quencher in close proximity. On hybridization to the target cDNA, fluorophore and quencher are separated, yielding signal. The GeneXpert assays are moderate complexity, with less than 15 minutes hands-on time required to pipette the sample into the cartridge and start the assay; results are available in less than 1 hour.

Highly Multiplexed Assays

Until recently, NAATs for infectious diseases testing were relatively simple, detecting at most eight targets because of limitations in sensitivity and specificity when attempting to detect multiple analytes. However, in recent years, highly multiplexed NAATs have been developed for the detection of a wide variety of viruses that might be present in a single clinical sample, providing the key advantage of traditional culture. Such so-called syndromic panels are best suited to sample types and situations in which a wide range of viruses (or other pathogens) may cause similar symptoms, such as with respiratory tract infections, meningitis/encephalitis, or gastroenteritis. Four main companies have developed panels to date, including Luminex, BioFire, GenMark, and Nanosphere, although several others have methods in development. The currently available diagnostic panels approved for use by the FDA are listed in Table 253.4. Some of these include detection of bacterial pathogens, yeast, or parasites. The primary value of these syndromic panels is improved sensitivity coupled with the detection of etiological agents that are not routinely tested for by other means (e.g., viral causes of diarrhea, coronaviruses in respiratory specimens, and parechovirus in CSF).⁵⁷

In the original Luminex xTag assays, viral nucleic acids are coextracted from specimens spiked with an internal control (MS2 phage), using an off-line automated extractor. Multiplex RT-PCR is then performed using primers specific to the viral targets and the control; these primers contain a tag sequence for target-specific primer extension (TSPE). The target-specific primers are then extended through addition of biotinylated deoxycytidine triphosphate to the reaction mixture, which is incorporated into the TSPE products. Following TSPE, products are mixed with color-coded microspheres with antitags. The antitag binds the tags present on the TSPE products, hybridizing the amplicons to the beads. The beads are read through solution-based microarray on the Luminex 100/200 or MAGPIX systems by two lasers—the first identifies the virus-specific color-coded bead, and the second determines whether amplicon is hybridized to the bead. The clinical performance of the xTAG Respiratory Virus Panel is well established, but the assay has several limitations. Sensitivity for certain adenoviruses (species C, serotypes 7a and 41) is poor, and primers for detection of rhinovirus cross-react with enterovirus.^{22,56,65} Similar to the Respiratory Virus Panel, the Gastrointestinal Pathogen Panel sensitivity is only 17.9% to 80% for adenovirus detection as compared to single-analyte PCRs.^{26,35} A key limitation of both the Respiratory Virus Panel and Gastrointestinal Pathogen Panel tests is the risk for false-positive findings as a result of cross-contamination by amplified nucleic acids, which are pipetted manually between stages of the assay. Additional limitations include time-to-results, which is 8 to 10 hours, and technical hands-on time. Luminex recently released the NxTAG Respiratory Pathogen Panel, which addresses many of these concerns. This method streamlines the process to include a single integrated multiplex PCR and bead hybridization step, which is followed by detection on the MAGPIX system. These modifications also reduce the risk for cross-contamination because the system is closed following addition of extracted nucleic acids to the test wells. Two studies have evaluated the NxTAG to date compared with singleplex RT-PCRs. Sensitivity for all targets was excellent, with the exception of the coronaviruses HKU1 and OC43, wherein only two of three specimens tested were detected,⁸ although a second study found 94% sensitivity for HKU1 and 100% for OC43.⁷³

Like the Luminex assays, the eSensor XT-8 (GenMark) is performed by extracting viral nucleic acids with addition of a bacteriophage internal control. End-point PCR is performed, after which exonuclease is used to create single-stranded DNA. This is hybridized to ferrocene-labeled signal probes specific to the different viral targets and application to a single-file microarray of preassembled gold-plated electrodes coated with single-stranded oligonucleotide capture probes. If present, target DNA-probe complexes hybridize the capture probes, binding the ferrocene label in proximity to the gold electrode; an electrical current is applied, and captured target DNA is analyzed by electrochemical detection using voltammetry. The eSensor XT-8 has excellent sensitivity and specificity for viral targets detected by the assay.^{60,62} The Verigene assays are performed on the Verigene processor, on which automated nucleic acid extraction, multiplexed RT-PCR, and hybridization to a slide array are performed. Detection occurs through Nanosphere's proprietary gold nanoparticle hybridization technology. Amplicons from RT-PCR are hybridized to a microarray followed by silver-coated gold nanoparticle probe hybridization. Product is detected by light scattering off the nanoprobe. Overall, the time to results is 2 hours, with very little hands-on time (pipetting of specimens to the test cartridge at the start of the assay and removal to the reader at the end of the assay). However, throughput is low, with only one sample per processor. The Verigene Flex Test includes detection of up to 16 viral and bacterial targets (see Table 253.4); however, users define which combination of targets are selected and reported at the time of test ordering. The laboratory is only charged for those analytes reported. Additional results initially not reported can be revealed, at an additional cost. Such a model has the advantage of allowing scalable respiratory virus testing for different patient populations, or during different respiratory seasons. From the laboratory perspective, testing is streamlined and economical.

Finally, the FilmArray panels (BioFire) are fully closed systems with a specimen-in, result-out format. These sealed systems minimize the contamination concerns associated with Luminex and GenMark assays. Nucleic acids are detected by a nested multiplex PCR; product is detected

using end-point melting curve data on the FilmArray instrument. The assay requires little hands-on time, and results are available in just over 1 hour. A significant drawback of the system is the throughput because only one sample can be processed on the instrument at a time. Thus larger laboratories may need multiple instruments to meet test volume. The FilmArray Respiratory Panel is cleared for the detection of 15 viruses and subtypes. Similar to the xTAG RVP assays, detection of adenovirus is problematic,^{18,59} particularly species C; serotypes 2 and 6 are poorly detected. The FilmArray Meningitis/Encephalitis panel includes several viral targets (see Table 253.4), with excellent sensitivity

and specificity compared with PCR, with the exception of human herpesvirus-6 (HHV-6), of which only 85.7% of cases were detected.⁴¹

Viral Nucleic Acid Quantitation Assays

Quantitative NAATs (qNAATs) play an important role in the diagnosis and management of viral disease.²⁷ Viral load assays are used to predict disease progression, distinguish symptomatic from asymptomatic infection, monitor the development of antiviral resistance, and assess the efficacy of antiviral therapy. Table 253.5 lists the FDA-approved quantitative molecular assays currently available.

CMV, Cytomegalovirus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; PCR, polymerase chain reaction; RT-PCR, reverse-transcriptase polymerase chain reaction.

qNAAT assays for the management of HIV were the first to be used routinely for the early detection of infection, resolution of indeterminate Western blot results, evaluation of suspected prenatal and intrapartum infection, and monitoring of the viral load for prognosis and evaluation of therapeutic efficacy. The goal of antiretroviral therapy is a reduction

of HIV-1 RNA below the limits of detection of the more sensitive assays (<20 to 75 cp/mL).^{27,70,76} Detection and quantitation of serum HBV DNA can assist in diagnosis of early acute infection, distinguish active from inactive infection, and monitor response to antiviral therapy. In early acute infection in which HBsAg is not detectable or yields equivocal

results, detection of HBV DNA may be used to make the diagnosis. Viral load can predict the course of chronic HBV infection as well. Viral loads are high in chronic active, replicative infection and are low or undetectable in chronic inactive infection. The aim of antiviral therapy is long-term suppression of viral replication; increasing HBV DNA levels may signal emergence of drug-resistant strains.^{30,75} Detection and quantitation of HCV RNA is useful for establishing the diagnosis of acute hepatitis before seroconversion, for detection of chronic HCV in seronegative patients, for resolution of indeterminate serologic results, and to monitor patients for disease progression and response to therapy.^{3,7,11,38} qNAATs are essential for management of chronic HCV. Viral load and genotype determine the likelihood of sustained viral response (SVR) and potential duration of treatment. Response to treatment is measured by achievement of SVR, defined as the absence of demonstrable viral replication 12 to 24 weeks after completion of a full course of treatment.

As is typical of other herpes group viruses, CMV possesses a high prevalence rate, establishes latency, and although usually asymptomatic in the normal host, causes disease in immunologically compromised hosts. Transplant recipients, patients with HIV or acquired immunodeficiency syndrome (AIDS), patients with cancer, and newborns are usually at highest risk for severe disease. Optimal patient management relies on laboratory testing. Quantitative assays are useful for early detection of CMV infection, differentiating latent infection from active disease, predicting disease progression, and monitoring response to antiviral therapy.^{14,37,72,77} In general, higher viral loads correlate with risk for disease development, and lower levels are associated with asymptomatic infection. Recommendations for serial monitoring using qNAATs have been published.^{14,37,72} Generally, threefold to fivefold changes in viral load may represent a biologically significant change in viral replication. Viral load thresholds that can guide therapeutic decisions in patient management across transplant groups are not yet well established because of variability in qNAAT assay design among laboratories and previous lack of a reference standard. The availability of FDA-approved assays calibrated against the World Health Organization (WHO) international standard should clarify interpretation of results and aid in the establishment of significant viral load thresholds within different immunosuppressed populations.^{14,72}

FDA-approved qNAAT assays do not exist for Epstein-Barr virus (EBV), BK virus (BKV), and adenoviruses; however, quantitation of these viruses is routinely performed.²⁷ As mentioned earlier, laboratory-developed tests vary in assay design and thus yield results that cannot be compared across laboratories. No standardized threshold values have been determined for the purpose of clinical management. Differences include specimen type (whole blood, plasma, peripheral blood mononuclear cells [PBMCs]) and volume, nucleic acid extraction method, PCR primers and probes, amplification chemistry, calibrators used to create standard curves, and result reporting (copies or IU per milliliter, copies per PCR, and copies per DNA concentration).

Conventional diagnostic methods generally are not useful in the evaluation of EBV-related disorders in immunosuppressed patients. Culture is not practical or useful, and serology is difficult to interpret in the setting of immunosuppression. PCR offers the possibility of rapid detection of EBV in a variety of clinical specimens and allows a semiquantitative or quantitative estimate of viral load. PCR has been used for establishing the diagnosis of AIDS-related central nervous system lymphoma, EBV-related lymphoproliferative disorders, and other EBV-associated diseases (e.g., infectious mononucleosis, fatal infectious mononucleosis, chronic active EBV infection, and EBV-associated hemophagocytic syndromes) in which increased DNA concentrations are associated with more severe clinical categories.^{34,53} PCR is particularly useful for the early identification and diagnosis of lymphoproliferative disorders (e.g., posttransplantation lymphoproliferative disorder [PTLD]) in pediatric patients after they have undergone liver transplantation, for monitoring EBV levels so that immunosuppression can be adjusted, and as a prognostic marker.^{28,53} Viral load measurement of EBV is routinely used to diagnose or predict impending PTLD. High levels are nearly always associated with PTLD, and increasing DNAemia predicts impending PTLD before appearance of signs and symptoms. Standardization of blood compartment used and calibration of qNAAT assays to

the WHO EBV standard should clarify significant quantitative thresholds for the management of PTLD.^{34,69} Primary infection with BKV typically occurs in childhood and usually results in chronic, asymptomatic infection in immunocompetent individuals. Whereas clinical disease is rare in immunocompetent adults, BKV infections are a significant cause of morbidity and mortality in immunosuppressed patients, particularly in renal transplant recipients and those with hematologic malignancies. Disease manifestations in renal transplants include BKV nephropathy (BKVN), which may result in renal dysfunction and graft loss. Asymptomatic hematuria, hemorrhagic cystitis, and renal impairment may occur in bone marrow transplant recipients and patients with hematologic malignancy. BKVN affects 1% to 10% of renal transplant recipients with frequencies of graft loss between 10% and 80% within 5 years. BKV quantitative PCR can facilitate early diagnosis of BKVN, guide management of immunosuppressive therapy, and monitor response to intervention. Prospective studies have shown that high-level BKV viremia (1–3 months after transplantation) precedes sustained viremia (1–12 weeks before polyomavirus-associated nephropathy [PVAN]), which in turn precedes allograft dysfunction. Reduction of immunosuppression or treatment with cidofovir when the viral load reaches a specific level has been associated with improved clinical outcomes. BKV quantitative cutoffs that indicated the need for renal biopsy were DNA loads greater than 10^7 copies/mL in urine or plasma loads greater than 10^4 that persist for longer than 3 weeks.^{58,66}

Human adenoviruses are associated with a variety of diseases affecting all organ systems. Most disease in immunocompetent individuals is self-limited; however, severe or fatal disseminated disease may occur in bone marrow, stem cell, or solid organ transplant recipients. Treatment includes administration of cidofovir and reduction of immunosuppression. Viral load testing is increasingly being used to predict disease dissemination ($>10^4$ copies/mL) and monitor antiviral therapy, although viral load thresholds are still to be determined.²¹

SUMMARY

Methods for the laboratory diagnosis of viral infections, including culture, SVA, antigen detection, and molecular diagnostic methods, have been reviewed. The use of these tests in some combination is most practical because a single test may not yield a diagnosis. For many viruses, culture has been the gold standard or reference method for evaluation of the new, rapid tests. However, culture is neither 100% sensitive nor always diagnostic of symptomatic infection. With the newer methods, particularly molecular diagnostic methods, the gold standard is changing, and evaluation of new techniques must be compared against a spectrum of laboratory and clinical data. Standards for performance and guidelines for the use and interpretation of molecular techniques are becoming available. Quantitative (vs. qualitative) viral results may be useful for interpreting tests, particularly with regard to viruses causing latent infection or for monitoring therapy or disease progression. Finally, interpretation of any result requires integration of the clinical history, laboratory data, treatment records, and observation of trends over time.

Parasitic Laboratory Diagnosis

David A. Bruckner • Robyn Shimizu-Cohen

Parasitic infections usually are associated with tropical areas; however, many infections (*Dientamoeba fragilis*, *Entamoeba histolytica*, *Enterobius vermicularis*, *Giardia duodenalis*, and *Toxoplasma gondii*) have worldwide distribution. With the ability of travelers to move freely throughout the world, clinical laboratories must be able to recommend specimen collection and detection and identification methods for all types of parasitic infections. It is helpful if the physician informs the laboratory of the parasitic infection that is suspected or the travel history of the patient because some organisms are detected more easily using specific methods (e.g., *Giardia* and *Cryptosporidium*—direct fluorescent antibody [DFA], enzyme immunoassay [EIA], or lateral flow assay [LFA] techniques) or alternative methods (e.g., microfilaria—Nuclepore filtration or Knott concentration procedure). The methods used, as with the rest of microbiology, are undergoing significant change, with a number of US Food and Drug Administration (FDA)-approved very sensitive nucleic acid amplification tests that can be used to detect a limited number of parasitic infections.^{6,7,12} These methods are slowly being adopted for use, so the older classical methods to detect infections still prevail.^{3,5,10}

The life cycle of the parasite and the time of infection are important factors in determining the type of specimens to be collected and the techniques used to detect the infection (Table 254.1). Multiple specimens might have to be examined before the etiologic agent can be detected (e.g., colon aspirates or biopsy tissue for *E. histolytica*, blood for malaria or acute Chagas disease). Detection of antibodies to *Taenia solium*, *Strongyloides stercoralis*, *T. gondii*, *Trypanosoma cruzi*, and *E. histolytica*

may be helpful in determining a diagnosis. All specimens must be considered infectious and must be handled with universal safety precautions using personal protective equipment (PPE).

The diagnosis of most parasitic infections is dependent on macroscopic or microscopic examination and antigen detection methods (DFA, EIA, LFA) of blood, feces, respiratory, tissue, and genitourinary specimens. Specimens must be collected using methods that allow for the preservation of parasites when they are transported to the laboratory. Most stool specimens are collected at home or in a physician's office that may be a considerable distance from the laboratory performing the stool examination. Trophozoites disintegrate rapidly and do not form cysts after passage; therefore stool specimens should be collected in containers from stool collection kits that have preservatives. The preservatives fix the specimens so that the trophozoites can be recognized easily on permanent stained slides and prevent the continued development of larvae and eggs. Exceptions to the use of preservatives involve new polymerase chain reaction (PCR) methods that use fresh stool or stool collected in Cary-Blair transport medium. In laboratories that have personnel with limited or no experience in detecting common or unusual parasitic infections, it is recommended that specimens be sent to referral laboratories with experienced personnel if there is reticence in performing routine examinations.

If questions of when and how to collect specimens to maximize the recovery of parasites occur, the specific laboratory to be used should be consulted about the collection methods of choice.

STOOL SPECIMENS FOR DETECTION OF INTESTINAL PARASITES

Liquid or semisolid fresh stool specimens should be examined within 30 to 60 minutes, respectively, from the time of collection for protozoan trophozoites. Because most clinical laboratories cannot perform the examination in this time frame, stool specimens should be placed in preservative immediately after passage (Table 254.2). Most stool collection kits contain a combination of vials such as sodium acetate–acetic acid–formalin (SAF) and polyvinyl alcohol (PVA); however, one-vial kits are becoming the system of choice. Mercury-, PVA-, and formalin-free

preservatives are commonly available. Specimens should be collected before radiologic examination with barium is performed, which may prevent the detection of intestinal parasites for up to 10 days after administration. Other substances or medications that also can interfere with the detection of intestinal parasites for a prolonged period of time include antibiotics (aminoglycosides, metronidazole, and tetracycline), antimalarial agents, bismuth, mineral oil, and nonabsorbent antidiarrheal agents. The specimen should be collected in a clean, wide-mouthed container and must not be contaminated with toilet water or urine. When collected, the specimen should be immediately transferred to a container with preservative. After being mixed with the preservative,

TABLE 254.2 Common Intestinal Tract Specimen Preservatives^a

Stool Preservative	Concentrate	Permanent Stain	Immunoassay	Advantages	Disadvantages
Formalin	Yes	No	Yes	Easy to prepare and has a long shelf life; preserves helminth eggs and larvae and protozoan cysts well; can be used with modified acid-fast and trichrome stains; can be used with most immunoassays	Does not preserve trophozoite morphology adequately; not suitable for permanent stains; specimen does not adhere to slide
MIF	Yes	No	No	Has a long shelf life; fixes and stains parasite forms simultaneously	Two solutions must be mixed immediately before use; trophozoite morphology is poorly preserved; not suitable for modified acid-fast or trichrome stains; iodine interferes with immunoassays
PVA	Yes	Yes	No	Excellent preservation of trophozoite morphology; suitable for PCR assays	Contains Hg, making disposal quite costly; morphology of larvae and eggs makes identification difficult; unsuitable for modified stains; PVA interferes with immunoassays
PVA, modified	Yes	Yes	No	Does not contain mercury; disposal is less expensive	Copper or zinc (substitute for mercury) does not preserve trophozoite and cyst morphology as well as mercury, making identification difficult; PVA interferes with immunoassays
SAF	Yes	Yes	Yes	Does not contain mercury; disposal is less expensive; has a long shelf life; permanent stain of choice is iron hematoxylin; preserves helminth eggs and larvae and protozoan cysts well; can be used with most immunoassays and special stains	Must use albumin-coated slides for permanent stains; contains formalin
Schaudinn	No	Yes	No	Excellent preservation of trophozoite morphology	Contains Hg, making disposal quite costly; not recommended for concentrates and has poor adhesive properties for liquid and mucoid specimens
Schaudinn, modified	Yes	Yes	Yes	Does not contain Hg, PVA, or formalin	Uses Zn as substitute for Hg May need to coat slide with albumin for better specimen adhesion.
Universal fixative (Total-Fix)	Yes	Yes	Yes	No formalin, Hg or PVA	

^aConsult product inserts to determine whether specimens in these preservatives can be used with special stains, immunoassays, or molecular testing. MIF, Merthiolate-iodine-formalin; PCR, polymerase chain reaction; PVA, polyvinyl alcohol; SAF, sodium acetate-acetic acid-formalin.

the specimen can be stored at room temperature until it is transported to the laboratory.

FDA-approved nucleic acid-based PCR testing is used to detect a limited number of intestinal protozoan infections and may include bacterial and viral causes of diarrhea in the same test. Specimens used in these assays are either fresh stool, stool placed in Cary-Blair transport medium, or preservative-fixed stool. Tests are of moderate complexity, and results are available in 1 to 5 hours. These tests are first-generation qualitative tests with a result of presence or absence of parasites. Multiplex assays may be less sensitive than single-plex assays. Quantitative assays may eventually prove to be useful to follow therapy, but these have not been applied to routine patient care in parasitology.^{2,4}

Physicians should recommend that three specimens are collected on alternate days within 10 days to rule out most intestinal infections. The probability of detecting stool parasites with a single stool specimen is as low as 50%. Multiple specimens collected from the same patient on the same day should not be accepted. Many intestinal protozoa, such as *Giardia*, have a cyclical population cycle, and the concentration

of trophozoites and cysts in the stool can vary considerably from day to day. Whether more than one specimen is necessary for PCR testing has not been evaluated.

OTHER SPECIMENS FOR DETECTION OF INTESTINAL PARASITES

Sigmoidoscopy samples may be submitted for the detection of *E. histolytica*. No fewer than six (mucosal) specimens should be submitted to the laboratory. Aspirates or scrapings can be collected and sent to the laboratory for direct wet mount observations, immunoassay, or PCR (not commercially available). Preservatives such as Schaudinn fluid or PVA can be used to fix the samples to microscopic slides. Biopsy specimens should be submitted to the pathology laboratory for histologic preparation.

Duodenal aspirates and biopsy specimens can be collected for the detection of *Cryptosporidium*, *Giardia*, and *Strongyloides*. Collection techniques similar to those mentioned for the detection of *E. histolytica*

can be used. In addition, duodenal contents may be sampled using the Entero-Test. The nylon string can be sent directly to the laboratory for processing and microscopic examination for parasitic organisms.

Strongyloides larvae might be detected in respiratory or other tissue and fluid specimens during autoinfection or hyperinfection cycles. Serologic testing can be used to detect *Strongyloides* infections with low worm burdens.

E. vermicularis infections are detected best using the cellulose tape method. Specimens should be collected in the early morning before bathing or having a bowel movement. The adhesive side of the cellulose tape is pressed against the anal folds; and after completion of sampling, the tape is placed with the adhesive side down onto a microscope slide. *Enterobius* eggs and adults may be trapped on the tape (commercial collection kits are available). Multiple specimens (four to six) may be collected on consecutive days to rule out the presence of infection. Eggs from infections with *Taenia* adult worms also may be detected using this method.

STOOL PROCESSING AND EXAMINATION FOR PARASITES

Stool specimens can be examined by light microscopically as wet mounts, concentrates, and stained slides; by DFA, EIA, LFA, and immunoblot for specific antigens; and by nucleic acid methods. Most of these techniques detect only a limited number of pathogenic parasites. To detect the majority of the stool pathogens, all specimens should be examined by microscopy using a concentration technique and a permanently stained slide (Fig. 254.1).

If fresh, unpreserved specimens are received, a direct wet mount should be performed for the detection of motile protozoan trophozoites and protozoan cysts. Helminth eggs and larvae also may be seen. If necessary, a few drops of saline may be used to emulsify the stool, and a drop is placed on a microscopic slide and covered with a 22 × 22 mm coverslip. The wet mount should be examined using ×100 and ×400 magnifications. A drop of iodine solution may be added to highlight parasite internal structures; however, parasite motility will be lost. A concentrate and a permanent stained slide also should be prepared from this fresh specimen.

Common concentration techniques include the flotation method using zinc sulfate (ZnSO₄) and formalin-ethylacetate sedimentation method. Specimens fixed in formalin, merthiolate-iodine-formalin (MIF), PVA, SAF, or Schaudinn can be used. The flotation method gives a cleaner preparation to observe cysts and eggs, but the high specific

gravity of ZnSO₄ tends to distort cysts and eggs, rendering identification difficult. Heavier eggs (e.g., *Ascaris* or operculated eggs) will not float and will be found in the sediment; therefore one should examine the surface film and sediment for a complete examination. The sedimentation method is used most widely in laboratories. Parasites and fecal debris are pelleted to the bottom of the tube by centrifugation. After the supernatant is discarded, the sediment is examined for parasites at ×100 and ×400 magnifications.

Permanent stained slides should be prepared on every stool specimen that is examined for ova and parasites. The stained slide is used primarily to detect and identify protozoa, trophozoites, and cysts. Gomori trichrome (Wheatley modification) and iron hematoxylin stains frequently are used in laboratories. Both stains have advantages and disadvantages that should be weighed, as should the expertise of laboratory personnel, before selecting the stain of choice for the laboratory.

Certain parasites are not detected easily by wet mount or routine permanent stained slides stained with Gomori trichrome (Wheatley modification) and iron hematoxylin. They include *Cryptosporidium* spp., *Cyclospora cayetanensis*, *Cystoisospora belli*, and microsporidia. The oocysts of *Cryptosporidium*, *Cyclospora*, and *Cystoisospora* can be detected by the modified acid-fast stain; however, some oocysts are refractory to stain. Similarly, the spores of microsporidia can be stained with a variety of stains, but not all spores stain evenly with the same stain.

Cultures of fresh stool or contents of the large intestine have been used to detect *E. histolytica*; however, this methodology is not practical for most clinical laboratories.

EIA, LFA, and immunoblot kits are commercially available for the detection of *E. histolytica*/*Entamoeba dispar* group, *G. duodenalis*, and *Cryptosporidium* spp. For the *E. histolytica*/*E. dispar* group, only fresh or frozen stool can be used in the assay. Formalin interferes with reagents to detect *E. histolytica* and cannot be used. EIA kits are available that will discriminate between these organisms using fresh or frozen stool. EIA kits for the detection of *Giardia* and *Cryptosporidium* can be used with fresh, frozen, or formalin-fixed stool. DFA tests have been developed to detect *Giardia* and *Cryptosporidium*. Depending on the manufacturer, either fresh or formalin-fixed specimens can be used.

PCR analysis also has been used to detect *E. histolytica*, *G. duodenalis*, *Cryptosporidium* spp., and *C. cayetanensis*, along with bacterial and viral pathogens. Specimens include fresh stool, stool placed in Cary-Blair transport medium, or preservative-fixed stool. Results can be available in 1 to 5 hours, depending on the manufacturer. These tests are expensive, but having a same-day result and increased patient satisfaction may outweigh the expense. If one PCR stool test can detect the same parasites

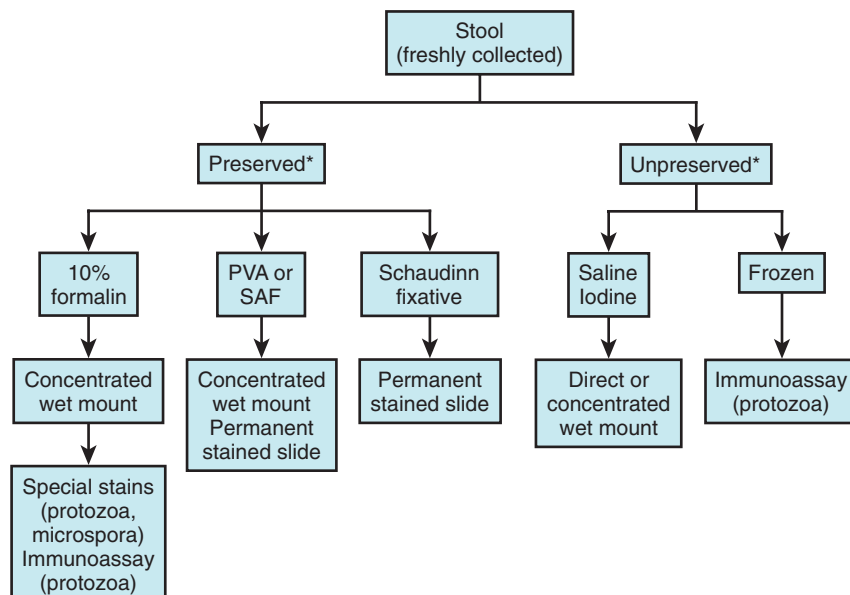

FIG. 254.1 Parasite stool examination. Asterisk, Worms (cestodes, nematodes, trematodes)—fix in 70% ethanol. PVA, Polyvinyl alcohol; SAF, sodium acetate–acetic acid–formalin.

that may require three stool specimens using routine methods, the cost will be nearly equivalent.

DFA, EIA, LFA, and immunoblot kits are readily available. DFA, EIA, LFA, and immunoblot kits have excellent sensitivity and specificity compared with microscopy. The disadvantage of using DFA, EIA, LFA, or immunoblot kits is that they detect only one or two pathogens at one time, so other pathogens might be missed. Additional parasite examinations would have to be performed to detect other parasitic pathogens.

Detection of *S. stercoralis* is enhanced by culturing a small amount of fresh stool on an agar plate and looking for larval tracks across the plate, as evidenced by lines of bacterial growth. Other methods include the Baermann concentrate, Harada-Mori, or Petri dish filter paper slant. It is possible that hookworm eggs could hatch, and the larvae would have to be differentiated from *Strongyloides* larvae.

BLOOD PARASITES

Although most laboratories will see blood parasites only during proficiency testing (Fig. 254.2), *Babesia* spp., *Leishmania donovani*, microfilaria, *Plasmodium* spp., and *Trypanosoma* spp. may be found.⁸ Depending on the parasite and infectious numbers, they may also be seen in cerebrospinal fluid, macrophages, plasma, tissue, or red blood cells. Maintaining proficiency to correctly identify *Plasmodium* to species or to recognize the amastigote stages of *Leishmania* is difficult for many laboratorians because these infections are seen so infrequently in the United States. Physicians should inform laboratory personnel about specific diagnoses or infections they are considering and the travel and medication history of the patient. If the patient took partial prophylaxis for malaria, a longer time should be spent examining the blood film owing to low parasitemia. Similarly, differences in periodicity of microfilaria in the blood exist, and the timing of collection of specimens becomes more important. Alternative concentration techniques not normally used in most laboratories, such as Nuclepore filtration or the Knott concentration procedure, can be used to detect microfilaria in low numbers. Without the knowledge of what infection the physician may be considering, these concentration procedures are not routinely performed on blood or other specimens, and the diagnosis of infections could be delayed or missed. Requests for the diagnosis of malaria must be considered to be STAT requests owing to the morbidity and mortality mostly associated with *Plasmodium falciparum* infections.

Although some parasites (trypanosomes and microfilaria) can be detected by their motility in whole blood, identification is dependent

on morphology as seen with a permanent stain. The blood film stain of choice is Giemsa, although Wright stain can also be used, or Delafield hematoxylin stain can be used for the microfilarial sheath. Because Giemsa stains may not differentiate the microfilaria nuclei adequately, Delafield hematoxylin stain may be necessary to speciate the microfilaria.

Blood films can be prepared in clinics or at the bedside (finger or earlobe sticks); however, the recommendation is that blood be collected in ethylenediaminetetraacetic acid (EDTA, lavender-topped tube) so that multiple slides (thick and thin blood films) can be prepared in the laboratory and antigen detection methods can be used. EDTA-collected blood provides the best overall morphology of parasites, and the tubes should be filled to the proper level to reduce distortion of the blood cells and organisms by the anticoagulant. Heparin tubes (green-topped tubes) also can be used; however, these blood-filled tubes cannot be used for PCR testing. The blood should be examined for parasites within 4 to 6 hours of being collected.

Blood should be drawn immediately when parasitemia is suspected. For malaria, blood should be drawn every 6 to 8 hours for 36 hours to rule out infection. Pediatric patients may have blood samples drawn at 10-hour intervals. One set of negative blood films does not rule out the presence of malaria. When the parasitemia level is low, procedures other than thick films, such as antigen detection, serology, or PCR analysis, may be the more sensitive method to detect *Babesia*, Chagas disease, malaria, or microfilaria. Serology has not been shown to be an effective method to detect active infections of African trypanosomiasis in nonendemic areas.

Blood Processing and Examination for Parasites

If the physician does not indicate the specific blood parasite suspected, fresh blood should be used as a wet mount to look for the presence of microfilaria or trypanosomes by their characteristic shape and motility. If these parasites are detected, a permanent stained slide will have to be performed to identify the organisms to species. When thick and thin blood films are examined for the presence of parasites, no fewer than 300 microscopic oil fields ($\times 1000$) should be examined before finalizing a result for the presence of *Babesia* or malaria. One may use lower magnification when looking for the presence of trypanosomes ($\times 400$) or microfilaria ($\times 100$), but the entire film should be observed before finalizing a result. Thin films are used for the detection of blood parasites, for enumeration of infected cells, and also to determine the species of parasite. When the films are air dried, the film can be fixed with 100% methanol and stained with Giemsa stain or Wright stain without the methanol

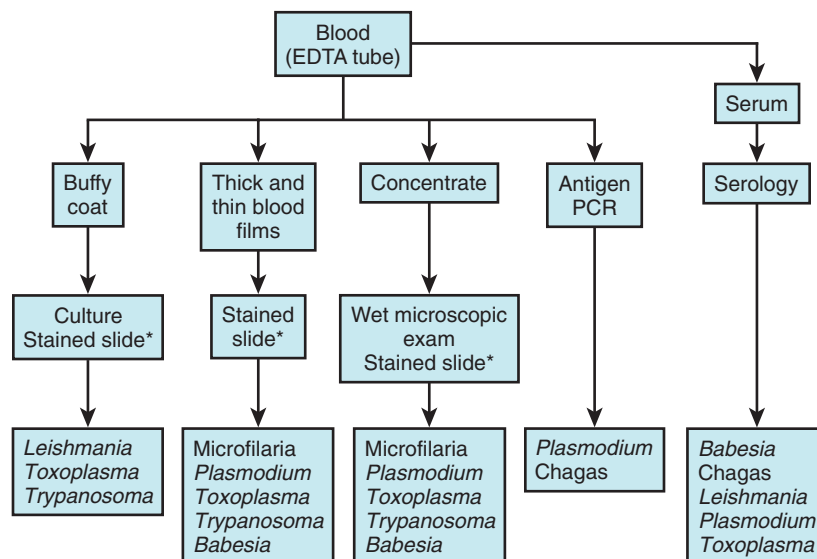

FIG. 254.2 Blood parasite examination. Asterisk, Preferred stain is Giemsa; however, Wright stain is also acceptable. EDTA, Ethylenediamine tetraacetic acid; PCR, polymerase chain reaction.

fixation process. If *Babesia* or malarial parasites (*P. falciparum*, *Plasmodium knowlesi*, and *Plasmodium vivax*) are present, one should quantitate the number of infected red blood cells. This quantification can be expressed as the number of infected cells per 100 red blood cells observed in the blood film. Serial specimens collected at various times during therapy can be used to monitor the success or failure of therapy. Continued presence of parasites in blood films without a marked decrease in parasitemia within the first 24 hours is an indication of therapeutic failure.

Thick films are prepared with one or two drops of blood that should be stirred in a small circle for 10 to 20 seconds at various intervals as it dries on the slide to prevent the blood from sloughing from the slide during the staining process. The thicker the film, the more likely the blood will slough. Detecting and identifying the presence of parasites on thick films is extremely difficult, particularly with inexperienced laboratory personnel. When the thick film has dried, the blood film is laked with water or buffer before staining if Wright stain is used, or the films can be placed directly into Giemsa stain without prior laking. Laking disrupts the red cell membrane, allowing the hemoglobin to be removed and leaving parasites, white blood cells, and platelets intact. The search for microfilaria can be performed at a lower magnification, whereas the search for *Babesia*, malaria, and trypanosomes must be done with oil magnification looking at 200 to 300 oil microscopic fields.

Concentration techniques also can be used to detect *Babesia*, *Leishmania*, malaria, microfilaria, and trypanosomes. Microhematocrit capillary tubes can be centrifuged, and the parasitized red blood cells and trypanosomes can be detected near the buffy coat interface. The tube can be scored and snapped, and the buffy coat can be used to prepare films. Alternatively, the tube can be observed under a microscope at the buffy coat interface for the presence of motile trypanosomes.

Microfilaria can be concentrated using the Knott procedure or Nuclepore membrane filtration technique. Normally, a 5- μ m filter is used, but if *Mansonella perstans* microfilaria is suspected, a 3- μ m filter is recommended. Most laboratories would not be familiar with or normally use concentration techniques unless specifically asked to do so.

Antigen tests for malaria have been developed and approved by the FDA for clinical use. These tests are extremely useful for laboratories that have limited expertise and exposure to specimens containing malaria or *Babesia*. It is difficult to differentiate malaria from babesiosis with infections when only very young trophozoites are microscopically observed. In this situation, the malarial antigen test can be very helpful. Antigens detected in these tests include histidine-rich protein-2, lactate dehydrogenase, and aldolase. False-negative antigen test results are known to occur owing to mutations of histidine-rich protein-2 in *P. falciparum* infection.¹ The sensitivity of the antigen tests to detect infections caused by *P. vivax*, *Plasmodium malariae*, or *Plasmodium ovale* is considerably reduced compared with *P. falciparum*.⁹ The histidine-rich protein-2 remains in the blood for a considerable period of time after therapy, so it cannot be used to follow therapy. False-positive antigen test results are known to occur in patients with hepatitis, leishmaniasis, rheumatoid arthritis, and schistosomiasis.

PCR testing for malaria is available from most referral laboratories, but it should not be used as the first test for the detection and identification of malaria. Blood films and antigen detection tests should be the first tests ordered.

The Centers for Disease Control and Prevention (CDC) have an excellent website (www.cdc.gov/malaria) on the detection and treatment of malaria.

UROGENITAL SPECIMENS

Trichomonas vaginalis is the most common parasitic pathogen; however, schistosome eggs, microfilaria, and microsporidia also may be recovered from urogenital specimens. Many *T. vaginalis* infections are diagnosed on clinical signs and symptoms without a specimen being collected. The detection of *T. vaginalis* usually is based on direct observation in wet mounts prepared from vaginal and urethral discharges, prostatic secretions, and urine sediment. Urine specimens should be obtained from first-voided urine in the morning. Specimens collected for the detection of *T. vaginalis* should not be refrigerated because *T. vaginalis* is susceptible to cold temperatures. Specimens can be diluted with a

drop of saline and observed under low power in reduced illumination for the presence of motile flagellates. Stained slides, such as Giemsa or Papanicolaou smears, also can be used, but the most infections with *T. vaginalis* are identified by the direct wet mount. This method is rapid and inexpensive; however, it lacks sensitivity, so there can be a significant number of false-negative specimens.

Culture (InPouch TV) can be used and is recommended by the CDC for patients suspected of harboring *T. vaginalis* infections when no organisms were detected by the direct wet mount method. Specimens can be collected with a brush, swab, or sponge. Specimens should be inoculated as soon as possible into the media. Cultures showing no organisms after incubation for 4 days can be reported as negative. When specimen transport is an issue, commercially available DFA, EIA, and nucleic acid detection kits are an excellent alternative. Nucleic acid amplification tests use the same transport as used for the detection of *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, including ThinPrep and SurePath transport. Use of this transport for the patient allows for only one specimen to be collected. Some nucleic acid amplification tests have results available in approximately 1 hour, making them comparable to the direct wet mount but with greater sensitivity.¹¹ The alternative detection methods can be quite expensive.

The Knott concentration procedure and the Nuclepore membrane filtration technique have been used for the detection of microfilaria in the urine. Microfilaria most frequently detected using these methods are *Wuchereria bancrofti* and *Onchocerca volvulus* (after therapy).

Schistosoma haematobium eggs found in the urine can be concentrated by sedimentation, centrifugation, or the Nuclepore membrane filtration procedure. The preferred specimen is urine collected at midday, when the patient is most active and most likely to have eggs in the urine.

Serology

A serologic diagnosis may be required when the parasites reside in tissues or other body sites and it is difficult to acquire a diagnostic specimen (e.g., in a patient with chronic Chagas disease or neural cysticercosis). Serology testing may also be useful when parasites, eggs, or larvae are in very low numbers in specimens and are difficult to detect (e.g., in a patient with babesiosis, fascioliasis, malaria, paragonimiasis, or strongyloidiasis).

A positive serologic test in an individual who resides in an endemic area must be interpreted with caution because the result may reflect past exposure and be unrelated to current clinical condition. A positive test in an individual without any past exposure may indicate a recent infection; however, this result must be correlated with the patient's clinical picture.

The detection of immunoglobulin A (IgA), IgE, IgG, and IgM antibodies to specific parasite antigens may or may not be helpful in establishing a diagnosis. With the exception of serology tests for the diagnosis of toxoplasmosis and the screening of the blood supply for antibodies to *Trypanosoma cruzi*, most of the other parasitic serology tests have limited laboratory availability. Although some of the tests have been validated as laboratory developed tests (LDTs), except for *T. gondii* and *T. cruzi*, there are no established external proficiency testing programs such as those offered through the College of American Pathologists. Even though the test methodology may be the same between different laboratories, reagents used in the tests may not have been standardized if they do not use the same kit manufacturer. This can lead to variable results.

In the United States, most serologic tests for the diagnosis of a parasitic infection are limited to the most commonly acquired extraintestinal infections. These are available at a few referral laboratories, specialized testing centers, and the CDC. Information on availability of parasite serology tests can be acquired from referral laboratories or from the CDC (DPDX@CDC.gov or 404-718-4100). The CDC offers the most comprehensive services for tests available and will also provide some information on unusual serologic testing not available in the United States.

OTHER SPECIMENS

Other important pathogenic parasites, such as ocular infections with *Acanthamoeba* and *Toxoplasma gondii*, can be detected in other anatomic sites and are addressed in specific chapters.
